Abstract

HIP 45734 is a quadruple system of 2 + 2 architecture located at 68 pc from the Sun. The outer 9″ system A,B has a period of ~10^3 yr. The subsystem Aa,Ab is a visual binary with a period of 20.1 yr and an eccentricity of 0.78. Its periastron in 2019.1 was observed spectroscopically, yielding masses (1.10 ± 0.04 and 0.98 ± 0.03 M☉) and orbital parallax, 14.90 ± 0.37 mas. The masses, luminosities, and colors approximately agree with evolutionary models of main-sequence stars. Component Aa has a detectable lithium line, whereas in Ab it is absent. The pair Ba,Bb is a single-lined spectroscopic binary with a period of 0.55552 day and an orbital inclination of ~45° derived by modeling the rotationally broadened line profile with flat bottom. The mass of Bb is ~0.4 M☉. Star B is chromospherically active (an X-ray source); its flux is modulated with the orbital period by starspots, in addition to occasional flares. The system is probably older than ~600 Myr; it does not belong to any known moving group.

Unified Astronomy Thesaurus concepts: Binary stars (154); Multiple stars (1081); Spectroscopic binary stars (1557); Visual binary stars (1777)

1. Introduction

Discovery of a population of young chromospherically active stars in the solar neighborhood by their X-ray radiation in the 1980s and 1990s stimulated follow-up observations to determine their physical parameters, ages, rotation, kinematics, etc. Many of these stars belong to young moving groups and associations (Torres et al. 2006). However, a large fraction (40%) are old short-period binaries (Makarov 2003). Recently renewed interest in nearby young stars is stemmed by the search for exoplanets using high-contrast imagers because young self-luminous planets are easier to detect compared to their older and cooler counterparts (e.g., Asensio-Torres et al. 2018).

The object of this note is a 9″ visual binary discovered by J. Hershel in 1837 and known as HJ 4214. Its secondary component B is called a T Tau-type star (Torres et al. 2006), probably because, apart from being chromospherically active, the stars are located in the sky close to the Chamaeleon star-forming region. However, the distance, the fast proper motion (PM), and the radial velocity (RV) make it clear that this pair is unrelated to the molecular cloud and only projects onto it. Common identifications and main parameters of the two visual components A and B are given in Table 1. The Gaia astrometry of star A is affected by its acceleration, leading to a larger parallax error compared to star B. The V magnitudes in Table 1 are calculated from the Gaia DR2 photometry using the prescription given on its website. The Tycho photometry gives 8.41 and 9.66 mag for A and B, both fainter compared to Gaia. Simbad gives for A the V magnitude of the combined light of A and B, 8.05 mag.

These stars, believed to be pre-main sequence (PMS), are featured in the large survey of Torres et al. (2006). The equivalent width (EW) of the lithium line in A and B was measured at 0.06 and 0.05 Å, respectively. Covino et al. (1997) took spectra of HIP 45734 together with other presumably young stars in Chamaeleon with a resolution of 10,000. They confirmed the presence of the lithium line and noted that the southern star B has emissions in the Hα, helium 5876 Å, and sodium D lines. Broad lines of star B resembled a blend, making Covino et al. think that B is a double-lined spectroscopic binary. However, no follow-up observations were conducted to determine the orbit. Desidera et al. (2006) also took high-resolution spectra of both visual components. They have not seen B as double-lined, but confirmed the strong Hα emission in its spectrum and its very high chromospheric activity index; the Hα emission in A was much lower. Thinking that B is a double-lined binary, Asensio-Torres et al. (2018) looked for low-mass companions around it using high-contrast adaptive optics, but found only a faint background source at 4″ separation.

Star A was resolved by Koehler (2001) into a close binary. Its first visual orbit with a period of 19.8 yr was computed by Tokovinin et al. (2015). My interest in this quadruple system is twofold. First, it belongs to the sample of solar-type stars within 67 pc (Tokovinin 2014), although the Gaia parallax now puts it just outside its distance limit. Spectroscopic observations were conducted to determine the unknown period of Ba,Bb, complementing the multiplicity statistics in this sample. On the other hand, the orbit of the interferometric pair Aa,Ab offered the prospect of measuring masses of young, possibly PMS, stars to test stellar evolutionary models. Both goals have now been reached and make the subject of this paper.

Figure 1 illustrates the architecture of this quadruple system according to this study. The pair Aa,Ab is a visual binary with an eccentric 20.1 yr orbit. It is composed of normal and apparently inactive dwarfs with masses of 1.12 and 1.0 M☉. In contrast, Ba,Bb is a close spectroscopic binary with a period of only 0.55 day. Star Ba, similar in mass to Ab, has a fast axial rotation synchronized with the orbit. Naturally, it is also highly active. The mass of the spectroscopic secondary Bb is about 0.4 M☉. Despite the short period, this pair is not in contact; it is not eclipsing owing to the large inclination.

Table 1
Main Parameters of HIP 45734

| Parameter | A | B |
|-----------|---|---|
| WDS       | J09194−7739 | HJ 4214, KOH 83 |
| Identifiers | HIP 45734 | TYC 9399-2452-1 |
| PM (mas yr$^{-1}$) | −106.8, 68.5 | −107.9, 70.8 |
| Parallax (mas$^a$) | 14.53 ± 0.15 | 14.66 ± 0.03 |
| Spectral type | G7V | K0IVe |
| V (mag) | 8.31 | 9.44 |
| G (mag) | 8.17 | 9.24 |
| K (mag) | 6.78 | 7.44 |
| RV (km s$^{-1}$) | 4.8 | 7.7 |

Note.
$^a$ Proper motion and parallax are from the Gaia DR2 (Gaia Collaboration et al. 2018).

Table 2
Parameters of the CCF Profiles

| Parameter | Aa | Ab | B |
|-----------|----|----|---|
| Amplitude | 0.242 | 0.161 | 0.053 |
| Amplitude × σ (km s$^{-1}$) | 4.28 | 4.07 | 38.7 |
| V sin i (km s$^{-1}$) | 4.7 | 4.0 | 67.4 |

and to estimate other parameters such as the line width and the related projected axial rotation V sin i. Average parameters of the Gaussian functions that approximate the CCFs are listed in Table 2. The rotational velocities were deduced from the width of the CCF dips for Aa and Ab and determined in Section 4.3 for B. The RVs and their residuals from the orbits are given below.

The CHIRON spectra show no emissions in the Balmer lines of component A, while these lines in component B are practically absent, being completely filled by emission. No other emission lines are detectable in either component.

The positional measurements of the pair Aa,Ab used for the calculation of its combined orbit are, mostly, made by the speckle camera at the 4.1 m Southern Astrophysical Research (SOAR) telescope. The instrument and data processing are described by Tokovinin (2018). The latest series of measurements and references to prior publications can be found in Tokovinin et al. (2019). The Washington Double Star Catalog (WDS; Mason et al. 2001) was consulted for the published measurements of the outer and inner resolved pairs. Since the first orbit of Aa,Ab was computed in 2014, 10 new speckle measurements covering the periastron have been made.

As in the previous papers of this series, orbital elements and their errors were determined by the least-squares fits with weights inversely proportional to the square of adopted errors. The IDL code orbit$^4$ was used (Tokovinin 2016b).

3. Subsystem Aa,Ab

The pair Aa,Ab was first resolved by Koehler (2001) in 1996. It was not measured in the following years, missing the periastron passage in 1999. The next measurements were made only in 2008 by Vogt et al. (2012) and in 2010 by Tokovinin et al. (2010). This pair has been followed by speckle interferometry at SOAR since 2011. The first visual orbit of Aa,Ab with a period of 19.8 yr was published by Tokovinin et al. (2015); it is refined here using both 10 new position measurements and 10 RVs (Table 3). The position measurements and their residuals are given in Table 4. All speckle measurements made at SOAR were re-examined and adjusted for slightly revised calibration parameters of each observing run, derived from wide pairs as described in Tokovinin (2018). The errors are assigned based on the data quality and used for setting weights inversely proportional to the square of errors. The weighted rms residuals from the new orbit are 1.4 mas in both directions. The orbital period is mostly constrained by the first observation in 1996 and the observations of the same orbit segment one revolution later, in 2015; the updated period is 20.1 yr (Figure 2).

The spectrum of A taken with CHIRON in 2015 had blended narrow lines of both components. In 2018 the lines separated further apart, then closed again and swapped after passing the periastron in 2019.1. The RVs of both components determined

from the CHIRON spectra and their residuals to the orbit are given in Table 5. The residuals are 0.05 and 0.17 km s^{-1} for Aa and Ab, respectively; I set the RV errors to 0.07 and 0.15 km s^{-1} to balance the relative weights of the RV and speckle data in the combined orbit. RVs derived from the blended CCF dips in 2015 were given a lower weight by assigning the errors of 0.2 km s^{-1}.

The accurate Gaia DR2 parallax of star B, 14.66 ± 0.03 mas, and the orbital elements yield the mass sum of 2.18 ± 0.09 M_☉. The mass sum error is mostly produced by the uncertainty of the a^2/P^2 ratio, estimated here by fitting 100 orbits where the input data are randomly perturbed by their nominal errors. This method accounts for the correlations between all elements. For example, the inclination i and the semimajor axis a are strongly correlated owing to the unfavorable orbit orientation. On the other hand, the Gaia parallax error does not contribute substantially to the overall mass error. The spectroscopic mass ratio q_{Aa,Ab} = 0.894 ± 0.007 leads to the individual masses of 1.15 ± 0.05 and 1.03 ± 0.04 for Aa and Ab, respectively.

Independently of the trigonometric parallax, the combined spectro-interferometric orbit leads to the masses of 1.10 ± 0.04 and 0.98 ± 0.03 M_☉ for Aa and Ab, while the orbital parallax is 0.99 ± 0.37 mas. I adopt the masses of 1.12 and 1.0 M_☉, compatible with both estimates within their errors. The orbital parallax agrees within its error with the Gaia parallax of component B. The mass measurement from the visual orbit and Gaia parallax is slightly less accurate than the mass measurement from the combined orbit. If Aa,Ab were a simple binary, rather than a quadruple, the situation would be worse because Gaia parallaxes of unresolved close binaries are less accurate and often biased. This will be corrected in the future Gaia data releases by incorporating orbital motion into the astrometric model and using ground-based measurements to extend the orbit coverage.

I compared the PM anomaly of star A (difference between its PM measured by Gaia with the mean PM derived from the Hipparcos and Gaia positions) given by Brandt (2018), (1.4, -0.8) mas yr^{-1}, with its value calculated from the orbit of Aa,Ab and scaled by the wobble factor f = -0.10 (see below), (1.1,-0.3) mas yr^{-1}. The agreement is satisfactory, considering that the Gaia PMs can be biased by the orbital acceleration of A.

4. Subsystem Ba,Bb
4.1. Spectroscopic Orbit

Component B was considered a spectroscopic binary by Covino et al. (1997) who believed to have seen double lines. My first observation with CHIRON in 2015 (Tokovinin 2015) showed a strange broad CCF dip with a flat bottom that resembled blended lines of two stars. However, further spectroscopic monitoring revealed that the CCF profile has a variable RV without changing its shape. Therefore, star B is a single-lined spectroscopic binary. Some spectra of B were taken with a resolution of 30,000, sufficient for measuring the RVs.

The CHIRON RVs lead to the unique orbital solution with P = 0.555 day (Figure 3 and Table 6). Approximation of the Π-shaped CCF by a Gaussian curve is poor, so the dip parameters in Table 2 derived from such approximation are inaccurate. I determined the average CCF profile and tried to fit it to each individual CCF. However, the resulting RVs were practically identical to the RVs derived by the Gaussian fits, hence I use the latter for consistency. The RVs and residuals to the orbit are given in Table 7. Despite the shallow and wide CCF, the rms residuals to the orbit are moderate, only 0.9 km s^{-1}; RV errors of 1 km s^{-1} are assumed. This provides an indirect evidence that the secondary component Bb does not contribute to the CCF. The lower panel of Figure 3 shows CCFs of component B ordered by the orbital phase. The CCF shape does not correlate with the phase and remains approximately constant.

The two crosses in Figure 3 denote the RV of B measured by Desidera et al. (2006) and the last CHIRON RV measured in 2019. If these RVs are used to fit the orbit, the residuals
increase substantially. A small drift of the period would explain this inconsistency, although its relative value is constrained by the available CHIRON RVs to within \( \sim 1 \) ppm.

\[ \text{Figure 2. Visual and spectroscopic orbit of HIP 45734 Aa,Ab (KOH 83). Left: orbit in the sky (scale in arcseconds, Aa is at the coordinate origin), center: fragment of the RV curve, right: CCF in 2018.2 with two resolved dips.} \]

| 58546.049  | 9.04                       | -0.40          | -0.09                      | -0.38          |
| 58621.5882 | 13.95                      | -5.27          | 0.04                       | -5.27          |
| 58800.8457 | 14.66                      | -5.94          | 0.03                       | -5.94          |

Micro-variability with the period of 0.5551 day was detected by Kiraga (2012) and attributed tentatively to component B. Therefore, Ba rotates synchronously with the orbit. The quoted amplitude of the variability, 11 mmag in \( V \) and 27 mmag in \( I \), refers to the combined light of A and B, hence the actual variability of B is \( \sim 2.5 \times \) larger. It is presumably caused by starspots.

The Transiting Exoplanet Survey Satellite (TESS; Ricker et al. 2014) recently furnished accurate combined photometry of stars A and B. I downloaded the aperture photometry of the short-cadence sequence provided by the TESS pipeline. The flux variation with the orbital period of Ba,Bb is obvious (Figure 4). Although the photometric period closely matches the orbital period, confirming the synchronous rotation of Ba, the shape of the light curve is not constant, reflecting varying distribution of spots. The variable peak-to-peak flux modulation corrected for the dilution by the light of A reaches almost \( \sim 0.1 \). Spikes in the light curves show flares in the active chromosphere of Ba.

Migrating spots affect the line profile of the fast rotator Ba and contribute to the RV scatter. Note that the CCF of component Ba (Figure 3) is slightly asymmetric, being lower on the right-hand side. This asymmetry does not change with orbital phase and could be of instrumental origin, given its subpercent amplitude. An asymmetry should cause a

\[ \text{Figure 3. Radial velocity curve of the subsystem Ba,Bb (top). The lower plot shows CCF profiles ordered by the orbital phase, written near each curve; the vertical dotted line marks the systemic velocity.} \]

\[ \text{5 https://mast.stsci.edu/portal/Mashup/Clients/Mast/Poral.html} \]
systematic positive shift of the RV, biasing the measured center-of-mass velocity of Ba,Bb.

4.3. CCF Profile and Inclination

The rotation of Ba is synchronized with the orbit. The RV amplitude, CCF profile, and photometry, considered jointly, lead to the estimation of the orbital inclination $i_{\text{Ba,Bb}} = 45^\circ$ and the mass of the secondary component, $\sim0.4\,M_\odot$. First, the absolute magnitude $M_V = 5.30$ mag and the effective temperature $T_e = 5250\,\text{K}$ of star B (see Section 6) allow for the calculation of its radius $R_\ast$ as $\log R_\ast = 0.5\log (L/L_\odot) - 2\log (T_e/5777)$. With the bolometric correction of $-0.24$ mag appropriate for the spectral type of B, this formula gives $R_\ast = 1.05R_\odot$. The Ba mass of $1\,M_\odot$ is assumed because the luminosities of B and Ab are equal.

Chromospherically active binaries of RS CVn type often have flat-bottom line profiles when the inclination is small. Hatzes et al. (1996) explained this fact by the presence of dark polar spots. To investigate this issue, I computed the broadening function of a rotating inclined star by dividing its surface into many small zones and summing up contributions of visible zones to the line profile. A plausible quadratic limb darkening (intensity drop from 1 at the center to 0.32 at the limb) was assumed. To account for possible polar spots, my model includes the latitude intensity dependence as $1+\alpha\cos\phi$ ($\phi$ is the latitude), where $\alpha > 0$ means dark polar spots and $\alpha < 0$ means polar brightening. The dashed line in Figure 5 is computed for $i = 45^\circ$ and $\alpha = 10$, i.e., $11\times$ dimmer at the pole than at the equator. The exact value of $\alpha$ does not matter when it is large, but small or zero values do not reproduce the flat-bottom line profile. The model qualitatively agrees with the shape of the CCF profile. However, a small maximum at the center appears only at inclinations $i \sim 20^\circ$, which would imply an unrealistically fast equatorial speed.

The FWHM of the CCF profile is 116 km s$^{-1}$. The FWHM of the modeled CCF profile equals $2 \times 0.86V\sin i$. The proportionality coefficient is almost independent of the inclination: $0.86$ for $i = 35^\circ$ and $0.84$ for $i = 55^\circ$. Hence, $V\sin i = 58/0.86 = 67.4\,\text{km s}^{-1}$. On the other hand, the equatorial speed of a star with $R_\ast = 1.05R_\odot$ and a period of 0.55 d is $94.7\,\text{km s}^{-1}$, therefore $i = 45^\circ$. At this inclination, the orbit gives the secondary mass of $M_{\text{Ba}} = 0.36\,M_\odot$ if $M_{\text{Ba}} = 1\,M_\odot$ is adopted. The mass ratio is $q_{\text{Ba,Bb}} \approx 0.4$. Large inclination implies the absence of eclipses, as observed.

Another estimate of the mass ratio, independent of orbital inclination and almost independent of the assumed mass of Ba, is obtained by comparison of the orbital and rotation speeds. For a circular orbit, the RV amplitude of the main star Ba is $K_1 = a\omega q\sin i/(1 + q)$, where $\omega = 2\pi/P$ is the angular speed
and $a = 3.15 R_\odot$ is the orbital radius, computed from the third Kepler’s law for the mass sum of $1.4 \, M_\odot$. On the other hand, $V \sin i = R_\odot \omega \sin i$. The ratio of these equations gives $q/(1 + q) = (K_0/V \sin i) \times (R_\odot/a)$ or $q = 0.36$ after substituting the measured and estimated quantities. The agreement with the mass ratio derived from the inclination is convincing.

The CCF profile of star B is displaced by the orbital motion by less than its half-width. This means that some areas on the stellar surface move in anti-phase with the orbit. Indeed, in the phased CCF profiles in Figure 3, the systemic RV marked by the vertical dotted line is always within the dip. The center of gravity of the system Ba,Bb is located inside star Ba at a distance of $a q/(1+q) = 0.83 R_\odot$ from the center. Despite the short period, the close binary system is well detached. The rotation is much slower than the break-up speed of $\sim 400 \, \text{km s}^{-1}$.

Spots on the rotating star Ba cause variation of its apparent RV. However, the semi-amplitude of the orbital motion, $54.93 \, \text{km s}^{-1}$, is substantially larger than any plausible effect of the spots. Moreover, the variable spot distribution (see Figure 4) would produce an irregular and variable RV curve, while the actual RV variation is sinusoidal and coherent on a time span of several years.

5. Outer Orbit

The projected separation between A and B is $s = 614 \, \text{au}$. If the orbit is circular and oriented face-on, $s$ equals the semimajor axis and the third Kepler law gives a period of $P^* \approx 8000 \, \text{yr}$ for a mass sum of $3.5 \, M_\odot$. The orbital speed is then $2\pi s/P^* = 0.5 \, \text{au yr}^{-1}$ or $2.4 \, \text{km s}^{-1}$ or $7.3 \, \text{mas yr}^{-1}$. If the pair A,B moved with this speed, its position would have changed by $1''3$ in the 180 yr elapsed since its discovery in 1837; such a displacement is measurable. In fact the pair moved much less, suggesting that the actual period might be longer and/or the apparent orbital motion in the plane of the sky is reduced by projection (Figure 6). The historical micrometer and photographic measurements recorded in the WDS have large random and systematic errors and do not help in elucidating the orbital motion of the wide pair, apart from the fact that it is substantially slower than expected for a face-on circular orbit. Modern measurements of A,B by Vogt et al. (2012) and Tokovinin et al. (2010) also appear somewhat discordant, likely because of imperfect calibration.

The most accurate measurements of the relative position of stars A and B (where A is the photocenter of Aa,Ab) are available from Hipparcos and Gaia on a time base of 24.25 yr. The pair has moved by $\sim -37.0 \, \text{mas}$ and $+20.4 \, \text{mas}$ in the radial and tangential directions, respectively. In 2015.5 the relative position of A,B was 194°13 and $8''988$. The relative positions of A,B can be described approximately by a tentative orbit ($P = 10^5 \, \text{yr}$, $T = 120$, $a = 10^6 \, \text{yr}$, $\epsilon = 0.2$, $\Omega = 11^5 \, \omega = 295^5$, $i = 85^5$). However, the orbit remains essentially unconstrained and these arbitrary elements have little value. According to this orbit, the motion is direct (position angles increase with time), but the Hipparcos and Gaia positions, after correction for precession, suggest a retrograde (clockwise) motion.

Gaia measured accurate PMs of stars A and B; their difference can throw some light on the motion in the wide pair. However, the orbital motion of Aa,Ab with a 20.1 yr period must be subtracted. The photocenter displacement of A is related to the relative position of Aa,Ab on its orbit by the wobble factor of $f = -q/(1 + q) + r/(1 + r)$, where $q = 0.89$ is the mass ratio and $r = 10^{-0.35 \lambda}$ is the light ratio of Aa,Ab, which depends on the wavelength. In the $V$ and $K$ bands, $r$ equals 0.59 and 0.70 and $f = -0.10$ and $-0.06$, respectively. According to the new orbit of Aa,Ab, in 2015.5 component Ab moved on the sky relative to Aa with the velocity of $(-15.7, +3.2) \, \text{mas yr}^{-1}$ in the R.A. and decl., respectively. The photocenter velocity scaled by $f = -0.10$ is $(1.6, -0.3) \, \text{mas yr}^{-1}$. The difference between the PMs of A and B measured by Gaia is $(1.1, -2.3) \, \text{mas yr}^{-1}$. Therefore, the orbital velocity of B relative to A was $(0.5, 2.0) \, \text{mas yr}^{-1}$. The tentative orbit predicts relative motion of $(-0.2, 1.8) \, \text{mas yr}^{-1}$. The motion in decl. agrees well and matches the historic trend of decreasing angular separation between A and B (B moves to the north toward A). The smaller motion in R.A. is of opposite sign. The discrepancy could be explained if star B had another low-mass companion with a period of a few decades. Yet, no such companion to B was found by high-contrast imaging (Asensio-Torres et al. 2018).

The measured difference between the RVs of B and A is $3 \, \text{km s}^{-1}$, of the same order of magnitude as the expected orbital speed of A,B. However, the center-of-mass RV of B is likely biased by the asymmetry of its wide CCF, hence the measured RV difference cannot be trusted. Qualitatively, it hints that the orbital motion in the wide pair A,B is directed mostly along the line of sight, while the motion in the plane of the sky is slower, as observed.

6. Photometry, Lithium, and Age

As components A and B are separated by $9''$, their individual photometry is readily available. The ratio of the CCF areas of Aa and Ab leads to the magnitude difference $\Delta V_{Aa,Ab} = 0.73 \, \text{mag}$ after correcting for the dependence of the line contrast on temperature. The latest speckle interferometry gives $\Delta V_{Aa,Ab} = 0.58 \, \text{mag}$, which I adopt here. The differential...
photometry of Aa, Ab by Vogt et al. (2012) is $\Delta K_{\text{Aa, Ab}} = 0.34$ mag, while Tokovinin et al. (2010) measured $\Delta K_{\text{Aa, Ab}} = 0.38$ mag and $\Delta H_{\text{Aa, Ab}} = 0.36$ mag. Therefore, the $V$ and $K$ magnitude of three resolved components Aa, Ab, and B are measured. Errors of ±0.02 mag in the magnitude and ±0.03 mag in the color index are assumed.

Using the Gaia distance modulus $4.169 \pm 0.005$ mag and assuming zero extinction, the components are placed on the color–magnitude diagram (CMD) in Figure 7. Components Aa and Ab are located very close to the main sequence. For reference, three PARSEC isochrones from Bressan et al. (2012) for solar metallicity are plotted. The Dartmouth isochrones (Dotter et al. 2008) were also tested. The 1 Gyr isochrone is similar to the PARSEC one, while the 50 Myr Dartmouth isochrone does not match the data.

Table 8 gives the measured magnitudes of three resolved components, the measured masses of Aa and Ab, and the effective temperatures deduced from the $V - K$ colors and isochrones. Gaia gives effective temperatures of 5760 K for A (close to the average temperature derived here) and 5242 K for B. The corresponding spectral types are G0V, G6V, and K0V (Pecaut & Mamajek 2013). Curiously, Gaia found an extinction of 0.45 and 0.32 mag in the $G$ band, assuming that A and B are single stars. However, there are no obvious interstellar adsorptions in the spectrum of A. Given the distance of 68 pc, an average extinction of $A_V = 0.1$ mag can be expected.

The colors, absolute magnitudes, and masses of Aa and Ab match the standard values of the main-sequence stars of spectral types G0V and G6V, within the uncertainty of both the data and the isochrones. The areas of the CCF dips of Aa and Ab correspond approximately to the stars of solar metallicity. Small triangles in Figure 7 show the locations of stars with the masses of Aa and Ab on the isochrones. The 50 Myr isochrone gives the best match, while at the 1 Gyr age the stars should be $\sim$0.2 mag brighter than observed. However, an extinction of $A_V = 0.2$ mag would remove the discrepancy. On the other hand, the rapidly rotating star B does not conform to the standard isochrones.

I do not see the 6708 Å lithium line in the spectrum of B because of its fast rotation and correspondingly low line contrast. The narrow-lined components Aa and Ab are resolved in the CHIRON spectra. Using the technique of Tokovinin (2016a), the lithium line in each component can be measured separately. Quite surprisingly, it is absent in component Ab, but prominent in Aa (Figure 8). Its EW is 30 ± 3 mÅ, less than 60 mÅ measured by Torres et al. (2006) from the unresolved spectrum of A. Component Aa contributes a $\sim$0.6 fraction of the flux, so the intrinsic EW of its lithium line is $\sim$50 mÅ.

At the age of the Pleiades, $\sim$150 Myr, stars with the masses of Aa and Ab have strong lithium lines with an EW of 120 mÅ (Soderblom et al. 1993b). In the Hyades, the EW is about 80 and 34 mÅ for stars with $B - V$ of 0.6 and 0.7 mag (Soderblom et al. 1993a). The presence of lithium in Aa and its depletion in Ab suggest that this system is substantially older than the Pleiades and maybe even older than the Hyades. However, lithium depletion depends not only on the age; this uncertainty prevents age-dating of HIP 45734 based on lithium. The isochrones in Figure 7 favor an age of $\sim$50 Myr, but their dependence on metallicity and the existing uncertainty of the stellar evolutionary models preclude any firm conclusions. An interstellar extinction of 0.2 mag would place stars Aa and Ab on the 1 Gyr isochrone. Moderate projected axial rotation of components Aa and Ab, $\sim$4 km s$^{-1}$, also suggests that these stars are not very young.

Component B (i.e., the combined light of Ba and Bb) is located above the main sequence. If the small contribution of star Bb, assumed to be an M3V dwarf, is accounted for, Ba moves in the CMD to the left by $\sim$0.15 mag, but still remains above the main sequence. The characteristics of Ba,Bb are reminiscent of post common envelope binaries, where a main-sequence dwarf is paired to a white dwarf (WD). The prototypical example, V471 Tau in the Hyades, has a spectral type of K1V, orbital period of 0.452, and a DA-type secondary component (Vaccaro et al. 2016), readily detectable in the UV.

Table 8: Parameters of Components

| Parameter | Aa | Ab | B |
|-----------|----|----|---|
| $V$ (mag) | 8.81 | 9.39 | 9.44 |
| $V - K$ (mag) | 1.44 | 1.66 | 2.00 |
| $M_\odot$ | 1.12 | 1.0 | 1.0 |
| $T_{\text{eff}}$ (K) | 5900 | 5590 | 5250 |

Figure 7. Location of components Aa and Ab (squares) on the color–magnitude diagram. The lines are PARSEC isochrones (Bressan et al. 2012) for solar metallicity and ages of 30 Myr, 50 Myr, and 1 Gyr; small triangles mark the masses of 1.12 and 1.0 $M_\odot$ on the isochrones. The locations of B and V471 Tau are shown by the diamond and triangle, respectively. The arrow corresponds to the interstellar extinction $A_V = 0.2$ mag.

Figure 8. Profiles of the lithium lines in components Ab (upper) and Aa (lower) are plotted by full lines, displaced vertically. The dotted lines are fitted Gaussians.
The above authors established that the mass of the red dwarf in V471 Tau is close to 1 M☉, contradicting its late spectral type and the low effective temperature of 5020 K. Obviously, this post-common-envelope star is not a normal dwarf. The same may be true regarding HIP 45734B. The position of V471 Tau in the CMD is marked by the large triangle.

7. Discussion

The Gaia distance and PM, together with the systemic RV of A, 4.88 km s⁻¹, correspond to the heliocentric Galactic velocity vector of \((U, V, W) = (-36.1, -15.9, -12.5)\) km s⁻¹. This velocity does not match any known kinematic group of young stars in the solar neighborhood. For example, the Hyades moving group has \((U, V, W) = (-39, -18, -2)\) km s⁻¹. The object certainly belongs to the Galactic disk. However, the weakly bound A,B pair would survive only if the ejection velocity were less than its orbital velocity (2 km s⁻¹), making the ejection scenario unlikely.

I looked for potential common proper motion companions in Gaia. All sources within 3° radius with parallax larger than 10 mas were retrieved; none match the parallax and PM of HIP 45734. The best candidate (09:42:33.853, -76:23:54.03), at 1°84 distance from HIP 45734, has a PM of \((-116.9, 65.9)\) mas yr⁻¹, parallax of 11.3 mas, and \(G = 18.08\) mag, hence it is not associated.

The secondary component in the Ba,Bb system is not detected spectrally or photometrically. It could be either a low-mass dwarf of spectral type M3 V or a WD. In the latter case, the short orbital period of Ba,Bb is a result of the common envelope evolution, like in the prototypical binary V471 Tau (Vaccaro et al. 2016). Another recent example of such object is Wolf 1130 (HIP 98906), where a late-M type subdwarf is paired with an unusually massive WD on a 0.5 day orbit (Mace et al. 2018). Old post-common-envelope binaries are chromospherically active and often masquerade as young stars. If component B is a WD, it could be detected in the UV. In the GALEX image of HIP 45734 (wavelength 0.231 μm), the southern star B is brighter than star A. However, chromospherically active stars are also strong UV and X-ray emitters. In short, the nature of star Bb remains unknown.

HIP 45734 is an excellent illustration of errors that could be made if the multiplicity were ignored or overlooked. A close binary Ba,Bb has a fast rotation and an active chromosphere and can be mistaken for a young single star. An unrecognized close unresolved pair Aa,Ab falsifies the determination of stellar parameters using standard relations (e.g., in the TESS input catalog), while its Gaia parallax is possibly biased. A wide binary A,B with a relative motion accurately measured by Gaia lends itself to a dynamical analysis of its orbit, but in fact its motion is strongly biased by the subsystem and the estimated components’ masses are also wrong if they are deemed to be simple stars.

This multiple system is less interesting than originally thought. It is certainly not a PMS object and is possibly older than the Hyades, although still younger than a typical age of the Galactic disk.

I thank the operators of the 1.5 m telescope for executing observations of this program and the SMARTS team at Yale for scheduling and pipeline processing. Re-opening of CHIRON in 2017 was largely due to the enthusiasm and energy of T. Henry. Two spectra were taken on my request by F. Walter. Comments by the anonymous referee helped to improve the presentation.
