ABSTRACT

We present the CoRoT light curve of the bright B2.5V star HD 48977 observed during a short run of the mission in 2008, as well as a high-resolution spectrum gathered with the HERMES spectrograph at the Mercator telescope. We use several time series analysis tools to explore the nature of the variations present in the light curve. We perform a detailed analysis of the spectrum of the star to determine its fundamental parameters and its element abundances. We find a large number of high-order g-modes, and one rotationally induced frequency. We find stable low-amplitude frequencies in the p-mode regime as well. We conclude that HD 48977 is a new Slowly Pulsating B star with fundamental parameters found to be $T_{\text{eff}} = 20000 \pm 1000K$ and $\log g = 4.2 \pm 0.1$. The element abundances are similar to those found for other B stars in the solar neighbourhood. HD 48977 was observed during a short run of the CoRoT satellite implying that the frequency precision is insufficient to perform asteroseismic modelling of the star. Nevertheless, we show that a longer time series of this star would be promising for such modelling. Our present study contributes to a detailed mapping of the instability strips of B stars in view of the dominance of g-mode pulsations in the star, several of which occur in the gravito-inertial regime.

1. Introduction

Asteroseismology, the study of stellar oscillations in order to infer information about the stellar structure, is a very powerful tool to improve our knowledge of the physics of stellar interiors (Aerts et al. 2010). Helioseismology, the seismology of the Sun, has helped tremendously in improving our knowledge of the Sun’s structure and interior physics (Christensen-Dalsgaard 2002). Asteroseismology is a younger but very dynamic field in astronomy, and several recent space missions, in particular MOST, CoRoT, and Kepler, have provided high-precision light curves for several classes of variable stars, including main sequence B stars (e.g., [Aerts et al. 2006b, Saio et al. 2007, Cameron et al. 2008, Haul et al. 2009, Neiner et al. 2009, Diago et al. 2009, Gutiérrez-Soto et al. 2009, Degroote et al. 2009, 2010, 2011, Pápics et al. 2011, Balona et al. 2011]). Despite these high-precision data from space, in-depth seismic modelling of most of these pulsating B stars must await (partial) identification of the wavenumbers of the dominant observed pulsation frequencies. This was only achieved so far for the Slowly Pulsating B (hereafter SPB) star HD 50230, which led to the conclusion that this star has an inhomogeneously mixed region surrounding its core (Degroote et al. 2010), and for the $\beta$ Cep star HD 180642 (V1449 Aql) which has an unusually high-amplitude dominant radial mode that induces several other lower-amplitude non-radial modes of the star through resonant mode coupling (Briquet et al. 2009, Aerts et al. 2011).

In the last decade, several asteroseismic studies of B stars based on large ground-based campaigns have been performed as well (Aerts et al. 2003a, Aerts et al. 2004a, Aerts et al. 2004b, De Ridder et al. 2004, Jerzykiewicz et al. 2005, Dziembowski & Pamyatnykh 2008, Handler et al. 2008, Brik et al. 2005, Handler et al. 2008, Desmet et al. 2009). These observations are very extensive and complicated, often involving multi-site multi-technique campaigns. Pulsating B stars typically pulsate with low-order $p$ and $g$ modes and some also experience high-order $g$ modes, making it necessary to observe them for a very long time in order to resolve all those modes. In addition, daily aliases are an observational difficulty since these stars often have (beat) periods of the order
der of a day. Nevertheless, ground-based asteroseismic studies of B stars have proven to be very successful and have led to important new insights in their interior physics. For example, it was possible to put limits on the value of the overshoot parameter of the core (Ausseloos et al. 2004; Dupret et al. 2004; Briquet et al. 2007; Desmet et al. 2009). From partially resolved multiples due to rotational splitting, it was also possible to show that some of those stars have non-rigid rotation, in the sense that their core regions rotate faster than their envelope (Pamyatnykh et al. 2004; Ausseloos et al. 2004; Dziembowski & Pamyatnykh 2008). Finally, the seismic modelling of those B stars provided values for their fundamental parameters, such as the effective temperature, log g and age.

In this paper we are concerned with data assembled with the CoRoT (Michel et al. 2006) satellite. Its main asteroseismology mission is to observe a limited number of bright main sequence stars during a long time span of maximum five months, but in between those long runs also shorter ones of some three to five weeks occur. Because of the success of the ground-based asteroseismology of B stars, several B stars with a variety of spectral type were selected as targets for CoRoT, with the aim to map the instability strips of the β Cep and SPB stars.

This paper is devoted to HD 48977, a B2.5V star (V magnitude of 5.92) which was observed by CoRoT as a secondary asteroseismology target during a short run in 2008. Its spectral type of B2.5V places it in the joint region of the SPB and β Cep instability strip. Very little was known about this star prior to the CoRoT observations. It had been flagged as a potential rotationally or pulsationally variable star and it was observed by Hipparcos, which led to a main frequency peak at 0.5218 d$^{-1}$ (Koen & Eyer 2002). Estimates of its fundamental parameters using colour indices were given in Lyubimkov et al. (2002) as $T_{\text{eff}} = 17500 \pm 300$, log g = 4.09 ± 0.08, from which the authors deduced $M = 5.7 \pm 0.3\, M_\odot$, $R = 3.6 \pm 0.4\, R_\odot$, an age of $30.6 \pm 10.7 \times 10^6$ yrs, and d = 252 ± 40 pc using Claret (1995) evolutionary tracks.

2. CoRoT high-precision photometry of HD 48977

HD 48977 was observed by CoRoT with a cadence of 32 s during a short run in 2008, from 2454531.48027JD (5 May) to 2454556.76361 (31 May), i.e., during some 25 days. The detrended light curve is shown in Fig. [1] It was obtained by fitting the light curve with a linear polynomial and dividing the light curve by this polynomial in order to convert to flux units and compensate for the loss of gain in the satellite CCD (Auvergne et al. 2009).

Searching for frequencies in the light curve was done independently by AT using Period04 (Lenz & Breger 2005) and by PD using the method in Degroote et al. (2009). The Fourier transform is shown in Fig. 2. It can be seen that the dominant signal occurs in the range below 3 d$^{-1}$, which is typical for g-mode pulsations in early B stars. The two methods give the same list of frequencies (within the resolution). The resulting 55 frequencies found having an amplitude more than 4 times the noise level are listed in Table 1. The main peak has a frequency of 0.5167 d$^{-1}$, very close to the frequency 0.5218 d$^{-1}$ of the Hipparcos light curve (Koen & Eyer 2002). We see that HD 48977 presents a rich spectrum dominated by g modes with frequencies between 0.1 d$^{-1}$ and 1.5 d$^{-1}$. We thus classify HD 48977 as a new SPB star.

An amplitude drop with a factor more than two occurs for the frequencies 35 to 55 in Table 1 which represent power in the p-mode regime, compared to the lower frequency regime (Fig. 2). While these 20 listed frequencies above 10 d$^{-1}$ are significant, we are cautious with their interpretation because they occur in the region where instrumental power also occurs (Auvergne et al. 2009), see also Fig 2. In particular, the two highest frequencies in Table 1 coincide with (daily aliases of) the satellite orbital frequency, keeping in mind the relatively large frequency uncertainty. Nevertheless, significant intrinsic stellar frequencies occur in the region [10, 20] d$^{-1}$. As is also the case for the pulsators HD 50230 (B3V, Degroote et al. 2010) and HD 43317 (B3IV, Pápics et al. 2012), the frequency structure in that regime is rather stable pointing towards p modes excited by the kappa mechanism. The autocorrelation of the power spectrum peaks

3. Spectroscopy of HD 48977

One high resolution high signal-to-noise spectrum of HD 48977 was obtained using the HERMES spectrograph (Raskin et al. 2011) at the Mercator Telescope. The normalised spectrum for the spectral range 4065-4155Å is shown in Fig. 4. It has a resolving power of 80 000 and a S/N ratio of about 170 in the region near the Si II doublet at 4128, 4130Å which is a spectral range most often used to study the oscillations of SPB stars (Aerts et al. 1999). From the Fourier transform of the SiII4567
Table 2. Si lines used to determine the effective temperature in B stars. Lines present in the spectrum of HD 48977 are underlined. Lines that should be avoided according to Simón-Díaz (2010) are listed in italic.

| Si II | Si III | Si IV |
|-------|--------|-------|
| 4128.054 | 4567.840 | 4212.405 |
| 4130.894 | 4574.757 | 6701.12 |
| 5056.150 | 4813.33 | |
| 6371.377 | 4829.073 | |
| 5716.287 | 5739.734 | |

after normalizing the spectrum, we measured the ratios of the equivalent widths (EWs) of the different ionization lines of Si, in order to obtain rough estimates of the effective temperature. Some Si lines appropriate for use in the case of B stars are listed in Table 2. Among those lines, all four Si II lines are present in the spectrum of HD 48977, while only three Si III lines are present and no Si IV lines. The lines present in the spectrum of HD 48977 are underlined in Table 2. Following Simón-Díaz (2010), some of those lines are badly understood from the viewpoint of atomic data and are better avoided in the analysis. Those lines are indicated in italic in Table 2. Looking at Table 2, we see that we can use only one Si II line and three Si III lines. The ratios of the EWs of the Si II and Si III lines are shown in Fig. 5 for log g = 4.2. The theoretical ratios are shown for two values of the microturbulence, namely $\xi = 1 \text{ km s}^{-1}$ (full lines) and $\xi = 5 \text{ km s}^{-1}$ (dashed lines), and for four values of the Si abundance, log(\(\epsilon(\text{Si})\)) = 7.54, 7.34, 7.14, 6.94 dex. This gives an estimate for the effective temperature of $T_{\text{eff}} = 19900 \pm 400 \text{ K}$. Given the fact that we have so few suitable Si lines, and for completeness, we did the same analysis using all the observed Si lines. From the lines that should not be used according to Simón-Díaz (2010), we get higher values for the effective temperature, up to 22000 K. This is consistent with the general trend reported by Simón-Díaz (2010).

After normalizing the spectrum, we measured the ratios of the equivalent widths (EWs) of the different ionization lines of Si, in order to obtain rough estimates of the effective temperature. Some Si lines appropriate for use in the case of B stars are listed in Table 2. Among those lines, all four Si II lines are present in the spectrum of HD 48977, while only three Si III lines are present and no Si IV lines. The lines present in the spectrum of HD 48977 are underlined in Table 2. Following Simón-Díaz (2010), some of those lines are badly understood from the viewpoint of atomic data and are better avoided in the analysis. Those lines are indicated in italic in Table 2. Looking at Table 2, we see that we can use only one Si II line and three Si III lines. The ratios of the EWs of the Si II and Si III lines are shown in Fig. 5 for log g = 4.2. The theoretical ratios are shown for two values of the microturbulence, namely $\xi = 1 \text{ km s}^{-1}$ and $\xi = 5 \text{ km s}^{-1}$ and for four values of the Si abundance, log(\(\epsilon(\text{Si})\)) = 7.54, 7.34, 7.14, 6.94 dex. This gives an estimate for the effective temperature of $T_{\text{eff}} = 19900 \pm 400 \text{ K}$.

In principle, the value for the microturbulence parameter can be found by looking at strong and weak lines of a given ion, and require that they yield the same abundances. Unfortunately, all O lines in the spectrum of HD 48977 are weak and we cannot determine the value of the microturbulence. It is, however, expected to be small for this spectral type. We included the unknown value of the microturbulence parameter for the element abundances by increasing the error bars based on two possible values of $\xi = 1 \text{ km s}^{-1}$ and $\xi = 5 \text{ km s}^{-1}$.

We can now obtain the abundances of the other elements with lines in the spectrum. The lines used for the analysis and the results obtained for the abundances are summarized in Table 3.

![Fig. 4](image-url) Excerpt of the high resolution high signal-to-noise spectrum (black) of HD 48977, obtained with the HERMES spectrograph attached to the Mercator Telescope. Grey lines indicate the zero-rotation line depths of a template spectrum with $T_{\text{eff}} = 20000 \text{ K}$ and log g = 4.2 dex (solar mixture and solar metallicity).

![Fig. 5](image-url) Theoretical EW ratios for log g = 4.2 of the suitable Si II and Si III lines in the spectrum with proper atomic data. Theoretical values are plotted for two values of the microturbulence, $\xi = 1 \text{ km s}^{-1}$ (full lines) and $\xi = 5 \text{ km s}^{-1}$ (dashed lines), and for four values of the Si abundance, log(\(\epsilon(\text{Si})\)) = 7.54, 7.34, 7.14, 6.94 dex. The two horizontal lines represent the observed values with their error bar.
The visual magnitude of HD 48977 makes it an optimal target for inclusion in wide-field surveys. We collected absolute photometry in the UV (TD1, ANS, Thompson et al. 1978, Wesselius et al. 1980, 1982), the optical (Strømgren, Lanz & Hubeny 2007). We deduced an effective temperature via the method of photometric determination of the effective temperature by roughly 1000 K compared to the silicon line ratios (Fig. 5) but the values are consistent within 2σ. Given the much higher quality of the HERMES spectrum compared to broad-band photometry, we adopt the spectroscopic estimate of the effective temperature.

5. Conclusions

From 25 d of CoRoT high-precision space photometry, we found the B2.5V star HD 48977 to be a new SPB star. In fact, it is the hottest confirmed SPB star known to date. In agreement with the star’s position in the joint part of the βCep and SPB instability strips, we detected numerous dominant g modes and low-amplitude p modes in its oscillation spectrum. The g modes occur in the frequency range 0.17 – 3.0 d⁻¹ and reach a maximum amplitude of 2000 ppm. The ratio of the p- and g-mode amplitudes of this moderately rotating star of solar metallicity is less than 0.025. In this aspect, the three stars HD 48977 (B2.5V, moderate rotator; this paper), HD 50230 (B3V, slow rotator; [Degroote et al. 2010]) and HD 43317 (B3 IV, fast rotator; Papics et al. 2012) are very comparable.

While the frequency precision is insufficient to perform forward modelling at this stage, an interesting aspect of HD 48977's variability is that we detected rotational modulation, in addition to the g-mode oscillations, in its photometric light curve, again similar to the case of HD 43317. The combination of the rotation frequency we found in the CoRoT light curve and the overall line broadening in the spectrum, implies that HD 48977 is one of the very few moderate rotators known within the class of SPB stars so far, the B3V star HD 43317 being an even faster rotator (Papics et al. 2012).

The rotation frequency of 0.6372 d⁻¹ is of the same order as the g-mode frequencies and implies that any future seismic modelling of the star must take into account the effects of rotation in the pulsation description. While this can be done using the traditional approximation for modes whose frequency is above twice
the rotation frequency (Aerts & Dupret 2012, Ballot et al. 2012), the lowest-frequency modes of HD 48977 correspond with so-called gravito-inertial waves and require a treatment not relying on perturbative methods (Ballot et al. 2010).

Our findings show that HD 48977 would be an excellent target for a long run during an extension of the CoRoT mission. This would probably allow to decide on the nature of the power in the frequency regime above $10^{-4}$ and to unravel rotational splitting of some of the pulsation modes, and hence would open stellar modelling applications from the mode identification of the multiplet structures.
