ABSTRACT

We present a set of 109 new, high-precision Keck/HIRES radial velocity (RV) observations for the solar-type star HD 32963. Our data set reveals a candidate planetary signal with a period of 6.49 ± 0.07 years and a corresponding minimum mass of 0.7 ± 0.03 Jupiter masses. Given Jupiter’s crucial role in shaping the evolution of the early Solar System, we emphasize the importance of long-term RV surveys. Finally, using our complete set of Keck radial velocities and correcting for the relative detectability of synthetic planetary candidates orbiting each of the 1122 stars in our sample, we estimate the frequency of Jupiter analogs across our survey at approximately 3%.

Key words: methods: data analysis – planets and satellites: detection – planets and satellites: gaseous planets – planets and satellites: individual (HD 32963) – techniques: radial velocities

Supporting material: machine-readable table

1. INTRODUCTION

The past decade has witnessed an astounding acceleration in the rate of exoplanet detections, thanks in large part to the advent of the Kepler mission. As of this writing, more than 1500 confirmed planetary candidates are known.7 The excitement of the modern exoplanet age is largely driven by the discovery of low-mass, potentially habitable planets detected through transit observations.

Figure 1 shows a mass–period diagram of the known planetary candidates. As is well known, three broad but well-separated families of exoplanets that have no counterpart in the Solar System populate the mass–period diagram: (1) close-in super-Earths, (2) hot Jupiters with P < 10 days, and (3) exo-Jupiters with P > 100 days.

At first glance, it is tempting to conclude that the Solar System is an outlier within the galactic exoplanet census. Martin & Livio (2015), however, argue that based on a number of metrics, the Solar System planets are relatively “typical,” concluding that Solar System analogs (and, by extension, potentially life-bearing planetary systems) might be common after all. They note that the main properties that distinguish the Solar System from other exoplanetary systems are the absence of very close-in terrestrial planets at P < 100 days (e.g., Chiang & Laughlin 2013), and the orbital location of Jupiter (P = 11.86 years, a = 5.2 AU, e = 0.05). They attribute the status of Jupiter as an outlier to observational bias, which favors short-period planets.

Given the importance of Jupiter in the dynamical history of our Solar System, the presence of a Jupiter analog is likely to be a crucial differentiator for exoplanetary systems. The dynamical evolution of Jupiter profoundly shaped the early history of the Solar System (see, e.g., Morbidelli et al. 2007). Recently, Batygin & Laughlin (2015) suggested that if Jupiter migrated inwards early on, it would have increased the rate of collisions between planetesimals, initiating a collisional cascade (Kessler & Cour-Palais 1978), and effectively clearing out the inner annulus of the Solar System (as well as potentially explaining the low mass of Mars as well; Walsh et al. 2011). With the formation of Saturn, a mean motion resonance with Jupiter was created, reversing Jupiter’s migration direction. In this picture, the Solar System was then left with Jupiter in a long-period orbit and small, gas-starved planetary bodies in the terrestrial region. The presence of a Jupiter-like planet in the system may also influence the habitability of Earth analogs (e.g., Horner et al. 2010). As a consequence, substantiating whether Jupiter lies at the edge of the exo-Jupiter locus, or is a typical member of an as-yet undiscovered population, may be key to constraining the frequency of true Solar System analogs and, by extension, worlds like Earth.

Current interest in the most prolific technique to populate the exo-Jupiter region of the mass–period diagram is radial velocity (RV) surveys. Unlike the transit method, which has a strong bias for short-period orbits, the RV method can probe the outer regions of extraplanetary systems over the bulk of the parent star’s lifetime. In order to safely detect a planetary signal, the minimum baseline is approximately 0.7–1 cycles (Wittenmyer et al. 2011), which translates to 5 ≲ Tmin ≲ 15 years for Jupiter-like planets. This period range has become fully accessible by established RV surveys over the past few years. Figure 2 shows a histogram of the baseline of the RV observations of stars. In our Keck sample alone, there are 793

7 See http://stefano-meschiari.shinyapps.io/PlanetPlot for an interactive mass/period/discovery method/discovery year plot.
stars that have been observed for more than 5 years and 489 stars that have been observed more than 10 years.

In this paper, we report that our set of 109 velocities obtained for the star HD 32963 (spanning approximately 16 years) strongly suggests the presence of a Jupiter analog with $P \approx 2372$ days (6.5 years), $M \approx 0.7 \, M_J$, $K \approx 11 \, \text{m s}^{-1}$, and $e \approx 0.07$. The host star can be considered a close solar analog (Porto de Mello et al. 2014), therefore making HD 32963 a benchmark for Jupiter analogs orbiting Sun-like stars.

Subsequently, we analyze a snapshot of our Keck sample of RV observations, and derive an occurrence rate of Jupiter analogs (defined here to lie within the parameter region with $5 \leq P \leq 15$ years, $0.3 \leq M \leq 3 \, M_J$, and $e \leq 0.3$), corrected for the relative observability around each of the 1122 stars in our sample. We find an occurrence rate of Jupiter analogs across our sample of approximately 3% for the period range spanned by our observations, consistent with previous findings (Wittenmyer et al. 2011). Under some reasonable assumptions about the underlying mass–period distribution of the Jupiter analogs, we find that the occurrence rate should lie between 1% and 4%. We conclude that the position of Jupiter on the “fringe” of the exo-Jupiter population is likely real, and that long-period Jupiter analogs are relatively rare.

The plan for the paper is as follows: in Section 2, we review the stellar properties of HD 32963 and our Doppler technique. In Section 3, we discuss our RV observations and the 1-planet model we use to interpret the RV variations exhibited by the star. In Section 4, we present a simple calculation to derive an estimate for the occurrence rate of Jupiter analogs. In Section 5, we discuss the HD 32963 system in light of the broader exoplanetary population and conclude.

## 2. STELLAR PARAMETERS

HD 32963 (HIP 23884) is a bright ($V = 7.6$) star. Porto de Mello et al. (2014) included this star in their study of nearby stars exhibiting similarities in their stellar parameters to those of the Sun. Using photometric and spectroscopic observations, Ramírez et al. (2013) derived $M \approx 1.03 \, M_{\odot}$, effective temperature $T_{\text{eff}} \approx 5727 \, \text{K}$, and age $\approx 4.9 \, \text{Gyr}$. Stellar parameters are reported in Table 1.

In order to evaluate the level of stellar activity, we obtained Mt. Wilson S-index values for each RV observation. The S-index measures the ratio of flux from 1 Å bins surrounding the line centers of the Ca II H & K lines (at 3968.47 and 3933.66 Å), as compared to two broader 25 Å bandpasses at 250 Å to either side of the Ca II H & K line location. The S-index is considered a proxy for chromospheric stellar activity, since it is correlated with the spot activity on the stellar surface. In turn, spots suppress RV shifts due to convection, leading to a potential correlation between the S-index and RV measurements and a long-term Doppler signal. This Doppler signal may

---

The box marks the region of parameters that we use to define a Jupiter analog ($0.3 < M < 3 M_J$ and $5 < P < 20$ years). The labeled points represent Jupiter, Saturn, and HD 32963 b. (Bottom) Period–eccentricity diagram of planets with $0.3 < M < 3 M_J$. We only consider planets with $e < 0.3$ as Jupiter analogs.

**Figure 2.** Histogram of the RV baseline for stars in our Keck sample. We highlight stars that have more than 10 observations separately.
have amplitude and periodicity mimicking the Keplerian signal from a distant planet. Therefore, we check for correlations between the S-index and the RV measurements as a standard step to identify stars with an ongoing magnetic cycle (Boisse et al. 2011).

Figure 3 shows the median S value for the stars in the current Keck sample. Isaacson & Fischer (2010) estimated a relatively low stellar jitter of approximately 2.615 m s$^{-1}$ (in this case, jitter is defined as the difference in quadrature between the rms of the velocities and the instrumental uncertainties). The top panel of Figure 4 shows a correlation plot of the RV observations and their S-index values. The correlation is computed at different values of observational lag (a lag of 0 corresponds to the same epoch for each RV and S-index observation). There does not appear to be any significant degree of correlation. Finally, we note that the Lomb–Scargle periodogram of the S-index observations shown in Figure 5 does not show any strong periodicity in the data (the strongest peak at 1282 days has a false alarm probability (FAP) of ≈14%).

Based on the lack of strong periodicities in the S-index time series and of any significant correlation with the RV observations, we conclude it is unlikely that the $K \approx 10$ m s$^{-1}$ is due to stellar activity.

2.1. Keck/HIRES RV Observations

We used the HIRES spectrometer (Vogt et al. 1994) of the Keck-I telescope for all the RV observations presented in this paper. Doppler shifts were obtained with the usual technique of impressing an iodine absorption spectrum on top of the collected light from the observed star (see e.g., Burt et al. 2014; Vogt et al. 2014, 2015, and others).

Table 2 shows the complete set of our RV observations for HD 32963. Our data set comprises 199 measurements over approximately 16 years (5838 days), binned into 109 measurements using 2-hr binning. The median formal uncertainty of the binned RV measurements is $\approx$1.2 m s$^{-1}$, with a velocity scatter of ≈8 m s$^{-1}$. Figure 6 presents the 109 individual Keck observations.

3. BEST-FIT KEPLERIAN MODEL

In order to ascertain the presence of periodic signals in the data, we computed the error-weighted, normalized Lomb–Scargle periodogram (Zechmeister & Kürster 2009), shown in the top panel of Figure 7. The three horizontal lines in the plot represent different levels of FAP (10%, 1%, and 0.1%, from bottom to top, respectively). The FAPs were computed by...
scrambling the data set 100,000 times and sampling the periodogram at 50,000 frequencies, in order to determine the probability that the power at each frequency could be exceeded by chance (e.g., Marcy et al. 2005). The bottom panel of Figure 7 shows the spectral window, displaying the usual peaks due to observational cadence, arising from the sidereal and solar days, the lunar month, and from the solar year (Dawson & Fabrycky 2010).

The tallest peak at \( \approx 2381.04 \) days has a \( \text{FAP} < 2 \times 10^{-5} \), much lower than the usual threshold for discovery (\( \approx 10^{-3} \)–\( 10^{-4} \)). Our procedure for modeling the signal is the same as that employed in Vogt et al. (2015); here, we briefly repeat the salient parts. We fit the radial velocities with a 1-planet Keplerian model, wherein we vary a vector of parameters consisting of the orbital elements (period, mass, mean anomaly, eccentricity, and longitude of pericenter). An additional term \( s \) is added in quadrature to the fixed, per-measurement observing errors \( e_i \) in order to model additional sources of scatter (e.g., underestimated measurement errors, stellar jitter, and other

(This table is available in its entirety in machine-readable form.)
astrophysical sources of RV variation). The best-fit parameters optimize the log-likelihood of the model:

\[
\log \mathcal{L} = -\frac{1}{2} \left[ \chi^2 + \sum_{i=1}^{N_i} \log(e_i^2 + s_i^2) + N_0 \log(2\pi) \right],
\]

where

\[
\chi^2 = \sum_{i=1}^{N_i} (V_i - v_i)^2 / (e_i^2 + s_i^2),
\]

and \(V_i\) and \(v_i\) are the predicted and observed RV measurements at time \(t_i\).

A simple Markov-Chain Monte Carlo algorithm (MCMC; e.g., Ford 2005, 2006) was used to derive the marginal distribution of the parameters of the model. The output parameters sample the posterior probability density given by Equation (1) and flat priors on \(\log P\), \(\log M\), and the other orbital parameters.

The final best-fit model is shown in Figure 8. Our model strongly indicates the presence of a single planet candidate (HD 32963b) with \(P \approx 2372\) days (6.5 years, \(a \approx 3.41\) AU) and \(M \approx 0.7 M_J\). The planet’s eccentricity is very low (\(e \approx 0.07\)) and consistent with 0. We note that there is a small linear trend in the residuals \((\approx 0.22 \text{ m s}^{-1} \text{ year}^{-1})\), which is fitted together with the planet’s orbital parameters (Figure 9).

The MCMC algorithm yields a set of fit parameters that sample the posterior distribution. We summarize these distributions by reporting the median and median absolute deviation (MAD) for each parameter in Table 3. We also show the marginal distribution of the model parameters in Figure 10, an orbital plot in Figure 11, and a full pairs correlation plot in Figure 12.

The bottom panel of Figure 8 shows the Lomb–Scargle periodogram of the residuals for the best-fit model. None of the peaks in the residuals periodogram is significant (FAP > 0.2).

4. THE OCCURRENCE RATE OF JUPITER ANALOGS

4.1. A Working Definition

The set of RV observations taken with Keck/HIRES, with its relatively uniform biases, long-term monitoring of hundreds of stars, and low formal uncertainties, offers a unique opportunity to probe the occurrence rates of long-period planets. In particular, we are looking to understand the frequency of exoplanets with properties similar to our own Jupiter and HD 32963b.

The first difficulty arises from establishing a definition for a “Jupiter analog.” This is a difficult and somewhat arbitrary task, since we do not have a full grasp of the population of exoplanets with \(P > 10–15\) years. We are interested in choosing orbital parameters such that, conceivably, planets falling in the parameter region chosen will play a similar dynamical role to Jupiter for their planetary system.

We approximately center our region of interest on Jupiter’s parameters. First, we chose to limit periods to the range between 5 and 15 years, between 3 and 6 AU for a solar-mass star (\(P_{\text{Jup}} \approx 11.86\) years, \(a_{\text{Jup}} \approx 5.2\) AU). The inner limit corresponds to the approximate location of the classical ice line. This range should roughly correspond to planets which formed close to the ice line and did not migrate more than a few AUs. The mass of Saturn (0.3 \(M_J\)) provides a natural lower bound for mass. We thus choose to limit our definition of

![Figure 8](image-url)
Jupiter analogs to the 0.3–3 $M_J$ mass range (i.e., within a factor of 3 of Jupiter’s mass). Finally, we require the eccentricity to be small ($e < 0.3$), an indication that the system did not undergo a period of strong dynamical instability after the dissipation of the protoplanetary disk.

Table 4 shows a list of known exoplanets that satisfy the above requirements, as listed by the Exoplanet Data Explorer in 2015 August (Wright et al. 2011a). The table also contains HD 219134 g (Vogt et al. 2015) and HD 32963 b. We excluded any star with an unpublished planet from the list.

### 4.2. Numerical Method

In this paper, we limit ourselves to a simplistic, yet straightforward re-derivation of occurrence rates for Jupiter analogs, following Wittenmyer et al. (2011).

Our database of RV observations consists of 1122 stars. In order to establish the number of Jupiter analogs that are detectable using our Keck data alone, we first fit each of the data sets individually, using an automatic fitting procedure analogous to that presented in Section 3. This procedure yielded 8 Jupiter analogs (a raw frequency of 0.71%; HD 134987 c is excluded because of the baseline requirement).

For each star, we computed synthetic data sets to derive the detectability of planetary signals. We created synthetic planetary signals over a uniform grid in $P$, $M$, $e$, and $\varpi$ combinations. Looping over the grid generates 320,000 planetary signals, which sample 20 values for $P$, 10 values for $M$, and 10 values for $\varpi$, and 4 values for $e$ (0, 0.1, 0.2, 0.3). Each of the 320,000 synthetic data sets is created by computing the Keplerian RV response at the observation times. We then degrade the observations by adding noise. The noise is derived by considering the residuals from the best fit (a proxy for the

![Figure 9. RV residuals for model that does not include a linear trend parameter. The best-fit linear trend is superimposed as a dashed line.](image)

![Figure 10. Marginal distributions of the orbital elements, drawn from 200,000 Markov-Chain Monte Carlo samples. The red dots mark the set of parameters with the highest likelihood.](image)
residual noise), scrambling them, and adding them to the synthetic RV data sets. We also sample the uncertainty associated with each timestamp to add additional noise to the data.

We then attempt to verify whether the synthetic planet is observable by evaluating the Lomb–Scargle periodograms of each synthetic data set. We require the peak corresponding to the synthetic planet’s period to have a FAP < 0.1% (computed analytically; Baluev 2008), and to match the original period within a 27% relative tolerance (Wittenmyer et al. 2011). We flag a synthetic planet as not detected if the above condition is not satisfied, or if the data set has less than 10 points, or if the observation baseline is shorter than 1 cycle. Finally, we compute the detectability at each (log $P$, log $M$, $e$) combination by averaging over the phases. The final output of this procedure is a recovery rate $f_{ijk} = f(P_i, M_i, e_i)$ for each star. Each element of $f$ varies between 0 (a planet at the given period, mass, and eccentricity would never be detected from the available data) and 1 (a planet at the given period, mass, and eccentricity would always be detected).

Figure 13 shows the completeness rate for circular orbits. The completeness is given by

$$f_C(P_i, M_i, e_i) = \frac{1}{N} \sum_{j=1}^{N} f_j(P_i, M_i, e_i),$$

i.e., the detection frequency averaged over all the stars in our sample. The value for each cell can be interpreted as the fraction of planets that would be detected, if every star in the sample hosted a planet at the cell’s period and mass. The median recovery rate is $\approx 19\%$ over the detectable period range (5–18 years), and $\approx 22\%$ over the period range for Jupiter analogs (5–15 years).

4.3. Results

We calculate the approximate frequency of Jupiter analogs for the Keck sample by considering the planets detected, and correcting for the expected completeness at their location in the $(P, M, e)$ space. The frequency is given by

$$F_{\text{jup}} = \frac{1}{N} \sum_{i=1}^{N_{\text{host}}} \frac{1}{f_i(P_i, M_i, e_i)},$$

(Wittenmyer et al. 2011). In Equation (4), $f$ is the recovery rate at the given period, mass, and eccentricity of the $i$th observed Jupiter analog, and $N_{\text{host}}$ and $N$ are the number of stars hosting a Jupiter analog (9) and the total number of stars (1122), respectively. Summed over the 8 detected Jupiter analogs, we get $F_{\text{jup}} \approx 3.0\%$.

In order to compute credible intervals for the occurrence rate, we used an alternative approach based on a simple Monte Carlo calculation. We draw $N_{\text{jup}}$ random parameter triplets for Jupiter analogs (comprising period, mass, and eccentricity), assign them to random stars in the sample, observe them with probability given by the recovery rate $f$, and finally require that the output number of observed Jupiter analogs be $N_{\text{jup,obs}} = 8$. For each input set of size $N_{\text{jup}}$, only a fraction will be compatible with the observed number of planets, yielding a broad distribution of $F_{\text{jup}}$. This approach has the advantage of yielding credible intervals for the occurrence rate of Jupiter analogs.

In order to draw the triplets, we consider a uniform distribution between 0 and 0.3 for eccentricity, and a period and mass distribution given by

$$\frac{dN}{d\log M d\log P} = N_0 M^\alpha P^\beta.$$

We consider two sets of $\alpha$ and $\beta$: a distribution that is flat in $\log P$ and $\log M$ ($\alpha = \beta = 0$), and the values derived by Cumming et al. (2008) by fitting the observed distribution ($\alpha = -0.31$, $\beta = 0.26$). The distributions yielded by our approach are shown in Figure 14, and the 10%–90% intervals are reported in Table 5. We find that the frequency rate of Jupiter analogs in our sample, based on this calculation, is likely no less than $\approx 1\%$, and no more than $\approx 4\%$.

5. Discussion

The Copernican principle (Bondi 1952) impresses the expectation that Earth, its position, and the architecture of the Solar System are not unusual, and by extension, it implies that Jupiter analogs are common. Seen from afar, Jupiter is the most detectable planet in the solar system (using either direct imaging, Doppler velocity, or astrometric monitoring). As a consequence, early speculative discussions of planet searches (Black 1980), as well as early detection efforts (Campbell et al. 1988) focused on detecting planets with masses and orbits similar to Jupiter. Observations have shown that giant planets occur within the full range of available parameter space, yet, the Copernican principle continues to strongly influence thinking. For example, there is little direct evidence that long-distance disk migration produces hot Jupiters, but the theory maintains its impetus in part because of the expectation that Jupiter-like planets should form at Jupiter-like distances beyond the protostellar “ice line” (Pollack et al. 1996).

Notwithstanding the detection of a new Jupiter-like planet on a Jupiter-like orbit around HD 32963, our analysis of over 1000 stars observed at Keck with precision Doppler spectroscopy suggests that Jupiter analogs have an occurrence rate of $\approx 3\%$ within our sample. Because of the gradual rate of data
accrual for long-period candidate planets, this result adds further weight to a consensus that has been emerging for some time. Cumming et al. (2008) analyzed 585 stars in the Keck Planet Search with \( N > 10 \) velocities (representing an 8-year subset of the data used in this study), and found an occurrence rate of less than 10.5% for planets with \( 0.3 \, M_J < M_p < 10 \, M_J \) and \( P < 2000 \) days; when extrapolated out to 20 AU, they also estimated an occurrence rate of \( \approx 3\% \). Gould et al. (2010), using the results of microlensing surveys, estimated a frequency \( f \sim 1/6 \) of systems orbiting \( M_* \sim 0.5 M_\odot \) stars that resemble the outer solar system (in that they contain planets with ice-giant masses and above in the region \( a \sim 3.5 \) AU. Wittenmyer et al. (2011), working with data obtained at the Anglo-Australian Telescope, found that approximately 3%, and no more than 37%, of stars host a giant planet between 3 and 6 AU from the parent star. Our result is consistent with all of these studies.

The relative paucity of Jovian planets with orbital periods of several thousand days has several seemingly straightforward implications. First, it could indicate that the migration of giant planets from beyond the ice line of the protoplanetary disk is indeed efficient, and that whenever Jupiter-mass planets form at \( a \sim 5 \) AU, they have little chance of staying there. In this view, the Grand Tack scenario (Walsh et al. 2011) provides an explanation for Jupiter’s current location by positing that the establishment of a 3:2 mean-motion resonance with Saturn fortuitously compelled Jupiter to return to the vicinity of its formation zone. Alternately, it might be difficult to fully complete core accretion at \( a \sim 5 \) AU in a typical protostellar disk. Accretion calculations (e.g., Hubickyj et al. 2005) suggest that proto-giant planet cores require disks with a high surface density of solids in order to form quickly enough to initiate rapid gas accretion within the confines of a typical disk lifetime. High-metallicity disks have higher surface densities of solids, and are presumably associated with high metallicity stars. This correlation is likely the source of the giant-planet stellar metallicity connection (Santos et al. 2001; Fischer et al. 2005; Gonzalez 2008), and suggests that true Jupiter analogs might be common only among stars within a particular metallicity range.
Long-running RV programs such as the Keck survey will continue to play a vital role in determining the architectures of the outer planetary systems orbiting nearby solar-type stars. Our work indicates that substantial efforts are still required to see a majority of Jupiter-like planets, despite the seemingly impressive $K = 12 \text{ m s}^{-1}$ RV half-amplitude that Jupiter induces in the Sun. Substantially more concerted efforts will be required to probe the frequency and orbital properties of ice giants with $P > 2000$ days. The planet Neptune, for example, if placed at 5 AU, would induce a mere $64 \text{ cm s}^{-1}$ signal. While potentially feasible, detections of such planets will require an excellent understanding of all sources of systematic error, both ground-based and astrophysical.

Figure 13. Survey completeness for circular orbits, given by averaging the detection frequencies over all the stars in the Keck data set at the given period and mass. The gray area indicates periods longer than the baseline of the RV data set ($P > 18$ years). The black dots mark the Jupiter analogs detected in the Keck sample.

Figure 14. Occurrence rate distributions for two different sets of $\alpha$ and $\beta$. We would like to thank Dr. Ramirez for useful discussions, and our referee for their useful critique.

D.R.’s research was conducted under the Byram Hills Authentic Science Research Program. S. M. acknowledges support from the W. J. McDonald Postdoctoral Fellowship and the Longhorn Innovation Fund for Technology grant. Astrobiology Institute under Cooperative Agreement Notice NNH13ZDA017C issued through the Science Mission Directorate. G.L. acknowledges support from the NASA Astrobiology Institute through a cooperative agreement between NASA Ames Research Center and the University of California at Santa Cruz, and from the NASA TESS Mission through a cooperative agreement between M.I.T. and UCSC. S.S.V. gratefully acknowledges support from NSF grants AST-0307493 and AST-0908870. R.P.B. gratefully acknowledges support from NASA OSS grant NNX07AR40G, the NASA Keck PI program, and from the Carnegie Institution of Washington. The work herein is based on observations obtained at the W. M. Keck Observatory, which is operated jointly by the University of California and the California Institute of Technology, and we thank the UC-Keck and NASA-Keck Time Assignment Committees for their support. This research has additionally made use of the Keck Observatory Archive (KOA), which is operated by the W. M. Keck Observatory and the NASA Exoplanet Science Institute (NExScI), under contract with the National Aeronautics and Space Administration. We wish to extend our special thanks to those of Hawaiian ancestry on whose sacred mountain of Mauna Kea we are privileged to be guests. Without their generous hospitality, the Keck observations presented herein would not have been possible. The authors acknowledge the Texas Advanced Computing Center (TACC, http://www.tacc.utexas.edu) at The University of Texas at Austin for providing HPC resources that have contributed to the research results reported within this paper. This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France, and the Exoplanet Orbit Database and the Exoplanet Data Explorer at exoplanets.org. This paper was produced using \texttt{Astropy}. Facility: Keck (HIRES).
