Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Review

Effectiveness of contact precautions against multidrug-resistant organism transmission in acute care: a systematic review of the literature

SUMMARY

Contact precautions are widely recommended to prevent multidrug-resistant organism (MDRO) transmission. However, conflicting data exist regarding their effectiveness. Prior systematic reviews examined contact precautions as part of a larger bundled approach, limiting ability to understand their effectiveness. The aim of this review was to characterize the effectiveness of contact precautions alone against transmission of any MDRO among adult acute care patients. Directed by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement, comprehensive searches of four electronic scientific literature databases were conducted for studies published in English from January 2004 to June 2014. Studies were included if interventional, original research, evaluating contact isolation precautions against MDRO transmission among inpatients. Searches returned 284 studies, six of which were included in the review. These studies measured four different MDROs with one study showing a reduction in transmission. Whereas studies were of high quality regarding outcome operationalization and statistical analyses, overall quality was moderate to low due to poor intervention description, population characterization and potential biases. Where compliance was measured (N = 4), it presented a threat to validity because it included select parts of the intervention, ranged from 21% to 87%, and was significantly different across study phases (N = 2). The poor quality of evidence on this topic continues to limit interpretation of these data. Hence, this conflicting body of literature does not constitute evidence for or against contact precautions. We recommend that researchers consider power calculation, compliance monitoring, non-equivalent concurrent controls when designing future studies on this topic.

Introduction

In 2014, the World Health Organization (WHO) declared antimicrobial resistance a worldwide problem that requires urgent action.¹ The WHO’s report states that most global regions have high rates of resistance to antimicrobial drugs among bacteria such as Staphylococcus aureus, Klebsiella pneumoniae, and Escherichia coli, and that these bacteria are
Multidrug-resistant organisms (MDROs) are considered to be serious threats to global security as infections with these organisms have higher mortality than those of non-drug-resistant strains, and are more difficult and costly to treat.\textsuperscript{1-4} Therefore, identifying and employing effective techniques to control the spread of MDROs is of high importance to manage health outcomes and reduce healthcare costs.\textsuperscript{3}

Isolation precautions are the preferred technique to control transmission of pathogens with high morbidity, mortality, or epidemiological significance, but controversy remains regarding the effectiveness of isolation precautions.\textsuperscript{3,5-10} This debate intensified following transmission of Ebola virus to healthcare workers despite use of isolation precautions.\textsuperscript{11} Like Ebola virus, MDROs are spread through direct or indirect contact.\textsuperscript{1} Therefore, contact precautions, which include isolation in a private room, if possible, and use of gowns and gloves, are recommended to reduce transmission of MDROs.\textsuperscript{6}

However, evidence regarding the effectiveness of contact precautions against MDRO transmission is limited in methodology and content. Prior studies have predominantly reported outbreak scenarios and therefore lack equivalent control group(s) and are subject to performance bias.\textsuperscript{12,13} Additionally, most have focused on meticillin-resistant \textit{S. aureus} (MRSA) or vancomycin-resistant enterococci (VRE).\textsuperscript{13} The effectiveness of contact precautions against emerging MDROs such as carbapenem-resistant \textit{Acinetobacter baumannii} and \textbf{\textit{β}}-lactamase-producing Enterobacteriaceae has not been established.\textsuperscript{14,15} More evidence may have become available regarding emerging MDROs since publication of previous reviews. Previous systematic reviews of this topic are similarly limited in the types of MDROs studied and outcomes measured, and have had mixed results.\textsuperscript{13,16-18} More importantly, contact precautions in all of these reviews were grouped with other infection control practices such as active surveillance.\textsuperscript{13,16-19}

Thus, gaps in the literature exist regarding effects of contact precautions alone and against emerging MDROs.\textsuperscript{14,15}

The objective of this systematic review is to characterize the effectiveness of contact isolation precautions alone against transmission of any MDRO among adult patients from interventional studies in which contact precautions are not included bundled with other interventions. In order to increase consistency between included studies and to better isolate the effect of contact precautions, this review focuses on acute care, as other settings such as skilled nursing facilities have different potential for infection transmission.\textsuperscript{20}

\textbf{Methods}

This review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement.\textsuperscript{21} Inclusion criteria for studies in this systematic review were: (1) original research, (2) published in peer-reviewed, scientific journals, (3) in English, (4) involved human inpatients, (5) conducted in acute care settings, (6) outcomes were infection or colonization with one or more bacterial organisms identified as multidrug resistant by the US Centers for Disease Control and Prevention (CDC), (7) experimental or quasi-experimental design (i.e. interventional), and (8) with intervention of contact isolation precautions (as either the control or experimental exposure).\textsuperscript{3} The components of contact precautions required for inclusion were: placement of the infected or colonized patient in a single room or in a cohort facility, application of standard precautions and disposable gown and glove use for close patient contact.\textsuperscript{6} Searches were limited to the past 10 years (January 1st, 2004 to June 2014) to target the most recent literature (i.e. with emergent pathogen outcomes), including that published subsequent to national clinical guidelines. Editorials, correspondences, commentaries, letters, or proceeding papers were excluded. Studies in which the effectiveness of isolation precautions was indistinguishable from that of a larger intervention bundle were also excluded.

\textbf{Search strategy}

With the help of a university librarian, searches of PubMed, Ovid Medline, EBSCO Cumulative Index of Nursing and Allied Health Literature (CINAHL) and Cochrane Central Register of Clinical Trials were conducted using the following terms: (1) isolation precautions, (2) multidrug resistance, (3) bacterial infections, and (4) healthcare-associated infection. The names of specific MDROs identified by the CDC were included as both keyword and medical subject headings (MeSH) terms, where applicable, to maximize search results.\textsuperscript{3} Searches also included synonyms, related phrases, and pluralized terms (see Appendix A, Supplementary material online). Hand searches of reference lists were also conducted.

\textbf{Study selection}

Two reviewers (C.C.C. and B.C.) screened search results to determine whether titles and abstracts met the inclusion and exclusion criteria. Full texts of articles were obtained and screened for eligibility when the title and abstract appeared to meet the criteria. All reasons for exclusion were recorded (Figure 1).

\textbf{Data abstraction}

A data abstraction tool of relevant criteria from The Cochrane Collaboration data collection form for intervention review of randomized controlled trials (RCTs) and non-RCTs was tailored for use in this review.\textsuperscript{22} C.C.C. pilot-tested the modified tool (see Appendix B, Supplementary material online) with two randomly selected eligible papers to confirm appropriateness of the tool and then used it to systematically collect data. These data included rationale for inclusion, methods, participants, intervention groups, outcomes, data and analysis, as well as funding sources, key conclusions, and reported conflicts of interest. C.C.C. contacted the publication’s corresponding author if study details were unclear.

\textbf{Quality appraisal}

Each study was appraised using the quality assessment tool that was developed, piloted, and employed by Aboelela and colleagues to review publications regarding isolation precaution effectiveness (see Appendix C, Supplementary material online).\textsuperscript{13} This tool has items regarding sample representativeness, bias and confounding, description of the intervention, outcomes and follow-up, and statistical analysis, which are each ranked 1–4, where 4 is the highest quality. Each paper was assessed as to whether it addressed the aforementioned
categories in a manner that was ‘completely adequate’, ‘partially adequate’, ‘inadequate, not stated or impossible to tell’ or ‘not applicable’. The authors performed component quality analysis independently and discussed results to consensus, as necessary. 23

Results

The search strategy described above returned 284 publications (Ovid: 165; PubMed: 112; CINAHL: 6; Cochrane: 1). Having excluding 129 duplicates, C.C.C. and B.C. reviewed the titles and abstracts of 155 remaining papers. Of these, 126 did not meet the inclusion criteria. The remaining 29 publications underwent full-text review. Hand search yielded five additional papers for eligibility assessment (Figure 1).

The most usual reasons for study exclusion were testing an intervention other than isolation precautions (N = 39) or a bundled intervention (N = 9); reviewing or presenting data that were not original (N = 28); describing the prevalence of MDRO (N = 17) or infection prevention practices (N = 14); or examining isolation through observation alone (N = 16). Of these, three attempted to estimate isolation precaution efficacy using mathematical models. 24–26

Characteristics of included studies

Six studies met the inclusion criteria and were included for the final review (Table 1). Four studies were non-randomized quasi-experimental studies comparing pre- and post-intervention MDRO rates, whereas two studies had a repeated treatment design. 27–32 One study took place during an MDRO outbreak. 32 Studies included in this review had four different MDROs as primary outcomes, many comparators, and varying methods of identifying MDRO colonization and infection. These fundamental differences prevented meaningful use of meta-analysis to evaluate the effectiveness of contact precautions against MDRO transmission. The small number of studies included in the review and difficulty in identifying and locating unpublished studies also precluded us from an assessment of publication bias. 33

Population and setting

Included studies were conducted in France, Great Britain, Israel, Hong Kong, and the USA. 27–32 Most studies were conducted in a single acute care centre (N = 5); one study included two hospitals with analyses done by subgroup. Four settings were noted as academic centres, another as a tertiary care

![Flow diagram of search results and eligibility analysis. Boxes on the left represent stages of evaluation of the publication returned through electronic database searches. The boxes on the right outline the number of articles excluded by the primary reason for exclusion. MDRO, multidrug-resistant organism; IP, infection prevention.](https://example.com/flow-diagram)

ICU, intensive care unit; MRSA, meticillin-resistant Staphylococcus aureus; VRE, vancomycin-resistant enterococci; CDI, Clostridium difficile infection; MDRO, multidrug-resistant organism; CI, confidence interval; EBSL, extended spectrum β-lactamase; CRKP, carbapenem-resistant Klebsiella pneumoniae; ED, emergency department; RR, risk ratio.
centre, and in one study the setting was not described. Studies took place in an intensive care unit (ICU); the other two applied their intervention throughout the whole hospital. Whereas most studies did not state inclusion or exclusion criteria for the individual patients, one indicated that all hospital admissions were included, and another included those admitted to the ICU for >48 h.

Interventions and comparisons

Almost all papers offered a description of the intervention. Two papers described the intervention by citing CDC guidelines. Variations to these practices and/or additional descriptions regarding the intervention were single-room isolation alone, staff cohorting, regular environmental cleaning and/or environmental cleaning at discharge and reserving healthcare devices (e.g. stethoscopes) for each infected patient.

Most studies (N = 5) compared the effectiveness of contact precautions with the effectiveness of another infection control intervention. These included universal gloving, gowning without moving infected individuals to private rooms, and cohorting patients and staff. Cohen et al. also included two additional phases of cohorting, which were increased surveillance in the ICU (phase 3) and active surveillance in the emergency department (phase 4). Bearman et al. also performed active surveillance, but it was not clear who was subject to screening. One study compared contact isolation precautions against no intervention to prevent transmission of MDRO colonization or infection.

In most of the studies, the authors initiated isolation precautions at the time of a positive MDRO culture (i.e. isolation was not pre-emptive) and the precautions were initiated for either colonization or infection. Some protocols included cohorting nurse staff members to care for the MDRO-positive patients. One study mentioned that it was possible for patients to be removed from isolation if the patient was MDRO-negative for six months. None of the publications included how long patients were observed to detect occurrence of the outcome. One publication noted that patients who were present during a study phase change were subsequently treated with the intervention of the new phase.

Five studies used pretests and post-tests to compare interventions in the different phases, though most aggregated results by phase or by year. Authors of one study compared MDRO infection rates between the pretest (phase 1) and the removed-treatment phase (phase 2), and phase 2 to the following phase where contact precautions were reintroduced (phase 3). Another study included a concurrent group, though this was a non-equivalent control as MRSA incidence

b Added to quality assessment tool described by Aboelela et al. (2006).
managed with contact precautions was compared to extended spectrum beta-lactamase (ESBL)-producing organism incidence managed with standard precautions (i.e. a different outcome was measured in each group).28

**Outcomes**

MDROs of interest in the included papers were MRSA, VRE, carbapenem-resistant Klebsiella pneumonia (CRKP), and drug-resistant A. baumannii.27–32 Three studies included measures of more than one MDRO: VRE and MRSA as primary outcomes and ESBL-producing organisms.28–30 All of the papers’ primary outcomes included colonization with the pathogen of interest in addition to active infection. However, screening procedures to identify cases differed substantially. One study tested the roommates, providers, and immediate environment of active cases to track pathogen spread (active, snowball sampling); another swabbed all patients for MDROs within 24 h of admission, weekly, at discharge, and as clinically indicated.27,31 Two studies tested participants on admission and then every four days or as clinically indicated; the other two tested for MDRO when deemed clinically necessary.26–30

**Analyses**

Two of the papers used Student’s t-test and χ² or Fisher’s exact test to compare continuous and categorical variables, respectively.27,30 Others used a Cox proportional hazards model, Poisson multiple regression analysis, or segmented linear regression (including change-point analysis).27,28,31,32 Two studies reported power calculations to ensure sufficient sample size to detect the anticipated change in infection rate, though in one of these studies the data analysis plan was amended and the power calculation was not changed to reflect the new strategy.27,31

**Study conclusions**

Five out of the six studies concluded that contact precautions did not represent a statistically significant improvement in MDRO infection control beyond that of the comparator(s).27,29–31 However, one showed a decreased colonization rate of drug-resistant A. baumannii during periods of contact precautions use compared to a period with no patient isolation (relative risk: 0.5; 95% confidence interval: 0.40–0.64; P < 0.001).32

**Quality appraisal**

Quality of the included papers ranged widely. Whereas overall quality could be considered moderate for each paper, poor performance on key quality items such as bias and confounding limited usefulness of this body of literature. Table II displays a visual representation of each paper’s quality along the concepts identified by Aboelela et al. All had at least one quality concept that showed clear opportunity for improvement. Gabaguidi-Hoare et al. did not have a portion of the quality appraisal tool that was deemed ‘inadequate’, but had more ‘not applicable’ items on the quality assessment tool. The following sections outline the rationale for the quality assessment of each paper.

**Representativeness**

Excepting Cepeda et al. which provided extensive details of the study setting, inclusion and exclusion criteria, and patient population characteristics, representativeness of the included studies was difficult to determine given the poor quality of population and inclusion criteria descriptions. The reviewers determined that most descriptions of the sample population were inadequate or partially adequate because these descriptions, if included at all, frequently lacked immunocompromised status or device use among the included sample, which are known risk factors for infection.3,27–30 Further, two studies explicitly stated the inclusion and exclusion criteria for enrolment of participants within these setting(s).27,31 Given that outcomes appear to include the whole unit or hospital, where no criteria were stated, the reviewers assumed that all patients were included in the study and determined this criterion to be ‘not applicable’ on the quality score. Nevertheless, failing to state this fact represents poor transparency of reporting. All studies provided adequate information regarding setting characteristics, including size and type of facility, type of unit (if applicable) and the hospital location. It was not stated in any study how settings and units within these facilities were chosen for participation, potentially subjecting the included studies to selection bias.27

**Bias and confounding**

The six papers received their lowest evaluations on the quality measures related to bias and confounding. Regarding the potential for sampling and selection bias, the reviewers assumed that the entire facility or unit was included unless otherwise stated. Therefore, the quality criterion for comparing the sample population characteristics to that of a larger population was deemed ‘not applicable’. The studies had wide quality variation in accounting for confounding interventions. The reviewers interpreted adequacy on this item as noting broad or systemic changes potentially affecting healthcare delivery and attempting to mitigate the effects of the confounder(s), where possible. Two studies were deemed completely adequate in this respect.28,31 Cheng et al. identified the severe acute respiratory syndrome (SARS) epidemic and corresponding systemic change as a potential confounder in their study and revised the statistical analysis to account for resulting bias. Cepeda et al. mentioned that environmental services protocols remained unchanged throughout the study and monitored hand hygiene to ensure consistent adherence rates. One study was deemed partially adequate as the facility ICU underwent renovations that doubled the number of beds in preparation for phase 2 of the study, though the authors confirmed that nurse:staff ratios were identical across the phases.30 This suggests that new nursing staff may have been hired. Though the presence of new personnel may lead to performance bias, this was not addressed in study design. Some studies were classified as inadequate due to inherent confounding in the study design itself, such as the addition of multiple ‘bundled’ interventions simultaneously.27 Others were considered inadequate because potential confounders, such as changes in unit occupancy and hand hygiene adherence, were tracked, but differences across study phases or groups were not accounted for in the statistical analysis.29
Further, Cohen et al. mentioned that national regulations for
infection control changed during the course of the study,
making it possible that a novelty effect may have presented a
threat to construct validity. Gbaguidi-Haore et al. mentioned
no potentially confounding interventions and that study was
therefore scored as ‘not applicable’ on this item.

The level of intervention compliance and quality of
compliance monitoring in these studies was mixed and often
inadequate. One did not track or report compliance. Another
reported compliance inconsistently across different phases of
the study, and others recorded compliance for particular
components of the intervention (e.g. gowning compliance
among nurses, but not among other healthcare workers). In
contrast, both articles by Bearman et al. measured compli-
ance for all components of the intervention and reported rates
during each phase. Given the compliance rates reported by
these studies, compliance was determined to be completely
and partially adequate, respectively.

Description of intervention

Half the studies’ intervention descriptions were completely
adequate. Those not deemed to be completely adequate
lacked descriptions of the compliance monitoring process,
whether gloves were donned upon contact with the patient’s
immediate environment during isolation, and how compliance
was enforced when enforcement was mentioned. Bear-
man et al. was inadequate on this item as description of the
survey component lacked critical information that would be
needed to repeat these methods, including survey format and
distribution.

Outcomes and follow-up

The majority of the included papers had high-quality oper-
ational definitions and assessment description such that
methods were reasonably repeatable. Four of six papers
completely addressed whether pre-intervention and interven-
tion phase groups were equivalent in follow-up/attrition by
showing that length of stay and/or death among participants
was equivalent between phases.

Statistical analysis

Statistical validity was generally acceptable in the included
studies. Three studies’ analyses were deemed ‘completely
adequate’, as each included appropriate statistical methods,
clear description of methods, and comparisons between
groups. The remaining papers were ‘partially adequate’
as they did not test for differences between groups or vari-
ability within them.

Discussion

We reviewed six studies regarding the effectiveness of
contact precautions against MDRO infections. Five of the six
studies did not find significant association between contact
precautions and reductions in MDRO transmission. One study
investigating contact precautions for A. baumannii colonization
or infection compared against no intervention
demonstrated a reduction in the number of cases in phases
where isolation precautions were implemented.

Limitations of this review are that it does not include papers
published in languages other than English or grey literature. As
with all literature reviews, it is also subject to publication bias.
However, our findings are consistent with previous literature.

Implications for clinicians

The quality of this body of literature does not justify
changes in practice. Conflicting data from studies with poor
design and/or low compliance does not constitute evidence
against contact precautions; rather, these data are inconclu-
sive. Whereas the study that performed best on our quality
score found no significance between contact precautions and
not isolating patients, this study did not consistently assess
intervention compliance in the various study phases. The
included study that showed a difference in MDRO transmission
with use of contact precautions did not report compliance
rates and could not be assessed for quality on any of the other
bias and confounding items of the quality assessment tool. Inconsistencies and absences in compliance monitoring and
reporting make it impossible to tell whether protocols were
completed as intended, threatening the internal validity of
these studies. The CDC recently faced similar difficulty
interpreting health outcomes after two healthcare workers
were infected with Ebola virus in Texas, as it was unclear
whether transmission had been due to inadequate isolation
precaution protocols or to a protocol breach. In practice,
healthcare facilities should be regularly monitoring compli-
ance, and investigating potential lapses when cross-
transmission is documented, to potentially resolve systems-
based inefficiencies. It is also important for researchers to
monitor and report compliance to understand what effective-
ness level can be reasonably expected in practice where
compliance may be lower than in clinical studies. Given the
quality of evidence presented here, it may be advisable that
healthcare workers and administrators continue to devote
focus and resources to improve components of contact pre-
cautions and other infection prevention techniques with strong
effectiveness evidence, such as hand hygiene technique and
compliance.

Implications for researchers

Although the included studies have limitations that have
been well described in the literature on this topic, such as lack
of intervention allocation concealment, some demonstrate
realistic opportunities for improvement in future studies. First,
two of the included papers contained a power calculation.29,31 As MDRO infections are rare events and most studies on this topic include small patient samples due to feasibility and cost concerns, future studies should also conduct a calculation to determine whether the study is adequately powered to detect differences in infection rates between intervention phases.12 Second, four of the included studies attempted to control for time trends in healthcare-associated infections and other confounders through statistical analysis.27,28,31,32 A concurrent, non-equivalent control, such as in Cheng et al., may address this issue, but concurrent controls are not always feasible. In the future, longitudinal studies with multiple pre-intervention collection points could add even stronger evidence by directly measuring and accounting for infection trends that are not related to the intervention, as in Bearman et al,38 Third, these studies differ from most previous publications by attempting to monitor intervention compliance.12,39 Previous studies that monitored compliance demonstrated improved adherence (i.e. with hand hygiene) when an isolation precautions intervention was implemented.40,41 However, this was not consistent with levels of compliance reported in the studies reviewed here.28–31 Low compliance with contact precautions could be the reason that this intervention appears to be equally or less effective than other interventions.51 This body of evidence demonstrates the implementation of a number of improvements in study design which, when combined in future studies, may yield substantially stronger evidence.

Another consideration for future studies is inclusion of patient-centred outcomes. Whereas benefits of isolation precautions are uncertain, adverse consequences of isolation precautions to the isolated individual, such as increased depression, anxiety, and anger, are well documented.42,43 A number of papers returned in our search discussed negative consequences associated with isolation, but none of the included papers incorporated patient-centred measures such as anxiety and depression.10,12,39,43–45 Considering that patient isolation is relatively resource intensive compared to other infection prevention activities, cost-utility analyses in future studies may be a good option to incorporate health outcomes, patient preferences, and costs to evaluate the effectiveness of contact isolation precautions against MDRO infection.46
