ABSTRACT

Woodlands in Kenya are undergoing land cover change and degradation leading to loss of livelihoods. Uncontrolled charcoal production, although a livelihood source for communities living in woodland areas of Kenya, leads to woodland degradation. We used Landsat imagery, field plot data and household interviews to describe land cover change and the role of charcoal production in woodland degradation. An unsupervised classification was used to determine land cover change from woodland to open/farmland, and five 16-km transects were used to investigate the extent of charcoal production in the target woodlands. Semi-structured interviews were conducted on 117 households to understand their perceptions on woodland cover change and the role of charcoal production. The overall accuracy of our classification was 86%. Woodland areas decreased by 24% between 1986 and 2014. The trend of woodland area change compared well between remote sensing and interview data. The density of kilns, a proxy for charcoal-led woodland degradation, varied across the sample plots. Despite charcoal providing a livelihood for 66% of the households, the community felt that their environment, wealth and social relations have been affected by land cover changes caused by charcoal production. Based on these results, we recommend that appropriate measures aimed at improving the productivity of agriculture, adapting to climate change and reducing dependence on charcoal for sustenance should be encouraged to mitigate woodland cover loss and degradation. KEY WORDS: charcoal; woodlands; Landsat imagery; community perceptions; land use

INTRODUCTION

Tropical savannahs and woodlands are a major component of the world’s vegetation, covering one sixth of the land surface and over half of the African continent. They account for about 30% of the primary production of all terrestrial vegetation, playing a crucial role in the energy, water and carbon balance (Ribeiro et al., 2013). Savannahs and woodlands provide a range of goods and services to humans in general and to local rural communities in particular (Pote et al., 2006; Kalema et al., 2015). Woodlands are therefore a key source of livelihood for over 50 million people in Africa (Campbell & Costanza, 2000). Ecological services provided by woodlands include soil quality maintenance through erosion and leaching protection (Ni et al., 2010; Zhang et al., 2015) thus avoiding erosion-induced soil quality deterioration that is a major impediment to global food and economic security (Ekkossa et al., 2015).

Woodlands and forests are key in regulation of water flow regimes and maintenance of morphology of water bodies (Keesstra, 2007; Keesstra et al., 2009), microclimate regulation (Belsky et al., 1989), carbon sequestration (Kalema et al., 2015) and economic benefits in the form of food and energy (Malimbwi et al., 2010). Despite their importance, tropical savannahs and woodlands are given less attention than tropical rainforest and other ecosystems in the land cover and land use change literature (Grainger, 1999).

Tropical savannahs and woodlands are among the most degraded and threatened ecosystems (MacFarlane et al., 2015). Degradation represents the temporary or permanent reduction in density, structure, species composition or productivity of vegetation cover (Malimbwi et al., 2010). It occurs when woodlands are not managed sustainably or controlled through appropriate environmental regulatory policies and frameworks (Bodart et al., 2013; Lemenih et al., 2014). Woodland degradation can have different drivers: overuse of resources, climatic conditions such as increased drought frequency, urbanization and agricultural expansion (Rocheleau et al., 1995; Le Polain de Waroux & Lambin, 2012).

In Africa, woodland degradation results from grazing, human-initiated fires for land clearing for agriculture and vegetation removal for fuelwood, charcoal and building material (Malimbwi & Zahabu, 2008; Ouedraogo et al., 2010). These activities can affect the structure and productivity of woodland areas, for example, by altering the soil properties (Yimer & Abdelkadir, 2010; Bruun et al., 2015; Mohawesh et al., 2015) and the hydrological regimes (Montenegro & Ragab, 2010; Yu et al., 2015). The way in which charcoal production links to deforestation and degradation has been debated (Chidumayo & Gumbo, 2013; Combes & Miltnner, 2016). Charcoal can lead to the transformation of woodland to bush and bush to scrub, over very...
large areas (Arnold & Persson, 2003). Charcoal making can occur when the land is being cleared for agriculture and thus may not be the main driver of degradation (Zulu & Richardson, 2013). In some cases however, charcoal production can be linked directly to woodland degradation (Chidumayo & Gumbo, 2013). Despite the unknown extent, woodland degradation because of charcoal production has been reported in Kenya (Kirubi et al., 2000; KFS, 2013).

The ongoing debate on the role and extent of fuelwood-driven degradation in woodlands (Butz, 2013) indicates that woodland degradation in arid and semi-arid areas is not sufficiently investigated. This is partly because woodlands are more difficult to monitor with traditional forestry tools and remote sensing as compared with other forest types. Woodland degradation is also more subtle than clear-cutting a forest making it difficult to detect its occurrence and extent. Moreover, woodlands are viewed as less commercially important (Grainger, 1999).

To obtain a comprehensive understanding of woodland degradation requires a combination of change detection by remote sensing, physical field observations and sociological data. The objective of this paper is to enhance the understanding of woodland degradation and to assess the role of charcoal making in woodland degradation for a study area in Kitui, Kenya using such a portfolio of methods. The novelty of this paper lies in linking woodland degradation and perceived change to livelihoods. We explicitly include perceptions by local inhabitants as this can provide information for planning (Vila Subirós et al., 2015) and gain support for restorative work (Davies et al., 2010) and better management of land cover change. We have chosen the woodlands of Kitui, Kenya as these have been undergoing rapid socio-economic, climatic and environmental change (Zaal & Oostendorp, 2002; Lasage et al., 2008).

Within this context, the specific aims of this study are to (1) investigate the spatial patterns and trends of local woodland degradation and cover change; (2) link woodland degradation with the perception of local people on the land cover/use change and the effect on their well-being; and (3) explore the role of charcoal in woodland degradation.

MATERIALS AND METHODS

The study area is located in Kitui County in Kenya about 150 km east of Nairobi (38°–23′, 38°–37′E and 1°–46′, 1°–58′S) and covers an area of 442 km² (Figure 1). The altitude is about 550 m above sea level. The average yearly rainfall for Kitui is around 1,000 mm with large local differences. The rainfall pattern is bimodal consisting of ‘long rains’ between March and May, while the ‘short rains’ season occurs between October and December (Lasage et al., 2008). The vegetation of the study area is described as Somalia–Masai Acacia–Commiphora deciduous bushland and thicket within the Somalia–Masai ecoregion (Brink & Eva, 2011) dominated by Commiphora spp., Acacia spp. and Adansonia digitata L.

The study area borders Tsavo East National Park to the south-east and Kitui South Game Reserve to the east. Mutha market is the largest settlement in the area. The land in the study area is privately owned through family lineages although formal titling has not been done. Shifting cultivation is practised within the family land holdings, which are generally a few kilometres apart. The population of the area is 10,154 people in 1,865 households (KNBS, 2010) with an average density of 27 persons km⁻² (KCDP, 2013). We selected the study site as it is located deep inside in the charcoal producing area of Kitui County. Furthermore, it is located at the intersection of two major roads connecting it to the Nairobi and Mombasa highway, where the charcoal is mostly transported to. Charcoal making was introduced in the study area in 1998 by evictees from Chyulu Hills in the neighbouring Makueni County about 120 km south-west of the study area, which was gazetted as a national park in 1995 (Muriuki et al., 2011).

Different methods were combined in order to analyse woodland degradation: land cover change detection based on the interpretation of satellite imagery, field-based charcoal site identification and interviews with local landowners. Figure 2 summarizes the data sources and processes followed to analyse the Kitui woodlands.

Landsat image analysis

We chose Landsat satellite images because they enabled us to work on a local scale of 30-m resolution and cover the desired time. Images for the years 1986 (26 August), 1999 (25 October), 2005 (22 August) and 2010 (1 June) were used (USGS, 2015). For 2014, we used a cloud-free mosaic from Hansen et al., (Hansen et al., 2013). The satellite images were chosen based on time of the year, their clarity...
and major socio-economic changes in the area (e.g. 1998 Chyulu Hills eviction). Images for the dry months were chosen to minimize the chances of error in classification because of seasonal differences in vegetation. The satellite images were pre-processed using ENVI 5.1 and ERDAS Imagine 9.1 software. We masked clouds—cloud cover however never exceeded 5% of the study area and was limited to the south-east section.

The unsupervised Iterative Self-Organizing Data Analysis algorithm was used to cluster image areas with common reflectance. We performed the classification in ERDAS with the convergence value at 0.95 and 20 maximum iterations, resulting in 20 clusters. These were later reclassified to three predetermined classes based on the knowledge of the area and visual examination of colour composites of raw satellite images (Stringer & Harris, 2014). The three classes were woodland, transitional woodlands and farmlands/open areas (Figure 3). It was not possible to map and analyse changes in the area occupied by settlements. This was because of the spatial resolution of Landsat images and the characteristics of mostly informal, small settlements, with a low share of sealed surfaces. The accuracy assessment was performed using a stratified random sample of 200 units, which were visually interpreted from the satellite images. We calculated the overall, user’s and producer’s accuracy for each classified image for the three land cover classes (Congalton, 1991; Foody et al., 2002).

A post-classification change detection was applied to analyse woodland degradation through space and time. The images from the different time periods were compared to create a change image map (Macleod & Congalton, 1998). This method has the advantage that various images are classified separately hence reducing the challenges associated with radiometric calibration (Singh, 1989; Lillesand et al., 2004).

Charcoal and woodland degradation

To further assess the impact of charcoal on woodland degradation, five parallel transects were aligned in a west–east direction. The transects, which were 16 km in length and 1 km apart, started from the Kivandeni-Mutha Market main road going towards the Kitui South Game Reserve boundary. They represent a gradient of accessibility as we assumed that accessibility might affect the degree of charcoal extraction (Figure 1). Rectangular plots (50 by 20 m) of 0.1 ha were sampled every kilometre along the transects, giving a total of 75 plots. The 50 by 20 m plot size has been widely used for assessments of shrub lands, tropical savannahs and woodlands (Luoga et al., 2002; Kalema et al., 2015). For every sampling plot, the global positioning system (GPS)
coordinates were captured and the number of charcoal kilns was counted. A kiln is an insulated chamber for wood carbonization made by covering a wood pile with herbaceous material and soil (Chidumayo & Gumbo, 2013, refer to Figure 3b). Furthermore, the number of tree stumps and species used for charcoal making within the plot was counted and identified with the assistance of local guides (Figure 3c). This plot level data was used as a proxy for the contribution of charcoal towards woodland degradation. The plot data was analysed using both inferential and descriptive statistics, including Pearson’s correlation coefficient. We also compared the reported kiln density with the land cover at the sampling plot locations within a 50-m buffer from the centre of the plot.

Comparison of woodland loss between remote sensing and community trends

In order to compare community knowledge and perceptions with remote sensing results, a total of 117 households were interviewed using a semi-structured questionnaire. The interviews were conducted between May and July 2015 by the lead author and four assistants whose mother tongue is the local language (Kamba). The assistants were trained on using GPS equipment and questionnaire administration. The questionnaire was also pre-tested to ensure appropriate wording and meaning of the questions. Systematic sampling of households was applied using eight transects evenly spread across the study area. The households interviewed were systematically picked at a distance of 1 km from each other along the transect. If no household was present after 1 km, the nearest household was picked. This method was adopted as there was no reliable settlement data or maps of the area available.

We targeted household heads (both male and female) who have lived in the area for at least 20 years to receive an accurate account of the past land use activities in the study area. The respondents were asked to explain the land cover changes within their holdings for the last 20 years, by indicating the estimated size of woodland and farmland within the land holding for 5-year time intervals. They were also requested to give their views on the impact of charcoal making on the land cover. Finally, the interviewees were asked to rate the effect of land cover change on their immediate environment, wealth and social relations on a Likert scale ranging from 1 (no change) to 6 (extreme change), as well as their motivation for the values given. In-depth semi-structured interviews have successfully been used to study stakeholder perceptions in land use and management (Teshome et al., 2014; Vila Subirós et al., 2015). Finally, personal observations of land cover/use types and sources of livelihoods were recorded to supplement the satellite, plot and community-based information.

RESULTS

Landsat image analysis and accuracy assessment

The results of the Landsat image analysis show the conversion from woodland and transitional woodland to open areas (Figure 4). The conversions from woodlands to transitional woodlands cannot always be related to human activity. For example, in several areas, we observed swaps between woodlands and transitional woodlands that were a consequence of seasonality and different levels of dryness in the area. The woodland area has been gradually declining in the study area from 1986 to 2014, from a total of 31,084 ha in 1986 to 23,930 ha in 2014 (Table I). The biggest change to the woodland land cover occurred between 2005 and 2014. Transitional woodland also increased but at a more moderate pace, from 9,966 to 11,572 ha. Although some changes to this class can be associated to land cover change, often these changes are a result of seasonality of woodlands. This is also shown by the fluctuation of the area covered by transitional woodland and the low classification accuracy of this land cover class. Overall, the results show an increase in farmland and transitional woodland areas at the expense of woodlands. There are few noticeable changes within the Kitui South Game Reserve.

The user’s and producer’s accuracy for woodland range from 84 to 98% (refer to Table II). The transition class has the lowest user’s accuracy of 69 and 75% for the year 2010 and 2014 respectively. This is because of the difficulty to map this particular land cover class.

Charcoal and woodland degradation

Evidence of charcoal making was recorded in 38 of the 75 sample plots. The number of kilns ranged from 1 to 6 (10–60 kilns ha$^{-1}$) per plot, and kilns had an average area of 25 m$^2$. The number of trees harvested per plot ranged from

| Overall  | 86                   | 89.5                     | 96                   | 87.5                     | 93                   | 93                       | 93                   | 93                       |                      |                          |
The perceived consequences of charcoal making and woodland degradation on community well-being are reported on a Likert scale ranging from no change (1) to extreme change (6) in Figure 8b. Less than 25% of the respondents believe that woodland degradation has had no impact on their immediate environment, wealth and social relations between 2010 and 2015, while at least 70% of the respondents ranked the effect as moderate to extreme change for the last 10 years. The reported aspects of environmental change mentioned overlap with the reported consequences of charcoal production, including increase in temperature, dust whirls and migration of bees. As a 45-year-old man from Kendoo village explained: “Bees have migrated. I have six bee hives out of which only one is occupied. The smoke from the kilns has driven the bees away”.

Reduction in harvest volume of maize and green grams (mungbeans) and the number of livestock are key reasons why respondents think that their wealth has gone down considerably. A 60-year-old man reported that: “I had 30 herd of cattle but now I have none. I used to harvest a lot of honey but now the bees are nowhere. I used to harvest 15 bags of maize but now I harvest 1 bag”. Perceived reduction in rainfall amounts and predictability has severely affected agricultural activities, and as a consequence, communal activities such as voluntary farmer self-help groups (mwethya) have since stopped. Exchange of agriculture-based gifts such as food items and livestock has also reduced. Overall, individuals have focused their time on daily survival efforts through non-farm activities such as charcoal making, small businesses and local employment. This shift in social relations is best captured through the sentiments
of a 60-year-old man from Ithango village: “we no longer share gifts, the mwethya no longer function and we no longer visit each other. We wake up early in the morning to search for food and return home late to sleep”.

DISCUSSION

Land cover change from satellite imagery

Although the use of satellite imagery to derive information on woodland degradation has its drawbacks, an 86% overall accuracy of our land cover classification indicates a sufficient level of accuracy to show real changes (Treitz & Rogan, 2004). Our accuracies are comparable to other studies in the region, for example, in Ugandan woodlands (Mwavu & Witkowski, 2008). Nevertheless, post-classification maps are subject to uncertainty, where the errors of individual maps propagate when different maps are compared to analyse land cover change (Olofsson et al., 2013). This can impact the validity of the observed locations and spatial pattern of woodland cover change. Additional confidence in the results is gained as the spatial pattern of woodland change follows a logical pattern near or adjacent to roads and settlements and is not randomly scattered across the landscape. Moreover, the change trends correspond well with the field measurements and interview results that each have their own, different uncertainties. By comparing different ways of measuring woodland change and degradation through a triangulation of evidence, we overcame the limitations of each individual approach.

The decrease of woodland area and an increase in farmlands in the study area are indicative for the rapidly changing land use regime in the area attributable to an increase in farmlands and shifting cultivation. This increase is partly because of population increase that rose from 3 persons/km$^{-2}$ in 1989 (CBS, 1994) to 11 persons/km$^{-2}$ in 1999 (KNBS, 2010) and drought adaptation mechanisms of the local population. Households have responded to the decreased rainfall amounts by clearing increasingly bigger farmlands hoping to compensate for lowered output per unit area. Our field observations point to shifting cultivation as one of the causes of woodland loss. Farmers use a particular portion of the farm holding for a period of time and clear a new woodland area for farming once the previous one is exhausted. The effects of shifting cultivation on reducing woodland cover have been reported in other African woodlands (Luoga et al., 2005; Kalema et al., 2015).

Conversion of woodlands to farmlands/open areas can have adverse effects on soils. Conversion of woodland to other land use has been noted to reduce soil organic carbon by 22–30% and total nitrogen by 19% for a study in Ethiopia (Yimer & Abdelkadir, 2010). An adequate amount of soil organic matter is considered essential for sustainable agriculture, and its reduction decreases crop productivity (Yimer et al., 2007). Loss of vegetation cover can lead to the formation of soil sealing that increases the risk of runoff and soil erosion. Mohammad & Mohammad (2010) reported high soil loss in cultivated fields as compared with land under woody vegetation, an observation they attributed to the breakdown of soil aggregate stability, loss of vegetative cover and exposure of the soil particles to direct impact of rain drops.

Charcoal as a driver of land degradation

Whereas population growth and the demand for cropland were the main drivers until 1999, charcoal burning became a significant driver of woodland degradation afterwards as evidenced by the large proportion of households who engage in charcoal production, the large number of kilns counted in woodland cover area and evidence of trees harvested for charcoal making. This is supported both by our field observations and interviews. It is not possible to attribute the drivers of woodland degradation directly from remote sensing data. The spatial pattern and distribution of woodland degradation derived from the remote sensing images after 1999 suggests charcoal burning among the major factors of degradation. Patches of woodland degradation after 1999 are smaller as compared with the ones between 1986 and 1999. The larger patches are likely the result of land clearing for agriculture, while the smaller ones are more characteristic for charcoal production. Nevertheless, it is difficult to point out one single driver, as often areas that had been cleared for charcoal production are afterwards used for cropland.

The degree of degradation is highly place-specific and depends on the density of preferred charcoal making species. Almost all the charcoal kilns were observed in woodland cover areas suggesting that charcoal making is an activity not directly associated with land clearing for agriculture. The role of charcoal making in land degradation has also been reported elsewhere (Luoga et al., 2002; Luoga et al., 2005; Chidumayo & Gumbo, 2013). As charcoal makers construct the kilns near the tree cutting site, kilns further contribute to degradation as they remain bare for a long time (Dons et al., 2015). Removal of vegetation cover and subsequent burning around charcoal kilns can result in soil fertility reduction. This can occur in numerous ways: soil erosion with nutrient loss on bare grounds, reduction of soil organic matter through volatilization and loss of soil microbial biomass because of increased decay and loss of heat-sensitive microbes (Certini, 2005; Zhang et al., 2015).

The effect of woodland degradation is further compounded by the presence of uncontrolled extraction roads that involves clearing of vegetation all the way to the kiln site. Furthermore, selective harvesting of preferred charcoal species may completely wipe away some species, changing the structure of the woodland and its ability for self regeneration (Butz, 2013). Many woodland and dryland species regenerate through coppicing (Sawadogo et al., 2002; McLaren & McDonald, 2003), and therefore, digging up their stumps severely compromises this ability (Malimbiwi & Zahabu, 2008).

It is difficult to relate woodland degradation to charcoal even with using relatively high-resolution Landsat images, as charcoal making is a phenomenon occurring at subpixel
size scale. To overcome this challenge, very high-resolution satellite imagery such as Quickbird and Ikonos are being used to analyse charcoal-related degradation (Oduori et al., 2011; Dons et al., 2015).

Extended droughts and low farm productivity are cited as some of the factors enhancing charcoal making in the savannah areas and Kitui County in particular (PISCES, 2010). With no other source of livelihood, poverty-stricken residents turn to charcoal making for subsistence and commercial purposes, as shown by other examples in Africa (Malimbwi & Zahabu, 2008; Kalema et al., 2015). People are attracted to charcoal production as it requires neither formal education nor large capital investment while at the same time charcoal is a cash product with a large market ready to absorb the entire production (Malimbwi & Zahabu, 2008).

The weak relationship between kilns and distance from the main road contrasts sharply with what is normally expected in wood resource extraction (Albers & Robinson, 2013). Studies in South Africa (Pote et al., 2006) have shown that the amount of harvesting decreases with distance from settlements as the most favoured species are removed first from accessible areas. The pattern in our study can be attributed to the nature of land ownership in the study area, local vegetation variations and the commercial aspect of charcoal making. Land is individually owned, and thus, owners can exert some degree of control on how trees can be used. The commercial nature of charcoal extraction, fuelled by demand for charcoal in cities such as Nairobi and Mombasa, has encouraged middlemen to venture deep into the woodlands, leading to charcoal production all over the woodlands. Charcoal can be sourced from long distances as long as the price increases result in marginal gain (Ahrends et al., 2010)

Comparison of woodland loss between remote sensing and community interviews

The high degree of similarity of woodland cover trends between remote sensing and from interviews indicates that the community is well aware of their surroundings and the land use changes. Combining interviews and remote sensing provides more reliable and comprehensive data on land use and land cover as various aspects of land use and cover change, their causes and effects can be clarified and verified. Also, several other studies have successfully compared satellite-derived land cover changes with interview data from multiple stakeholders ranging from farmers, communities, businesses and institutions. In these studies, the interviews focussed on identifying the drivers of change (Malek et al., 2014; Ariti et al., 2015), the impact of changes (Garedew et al., 2009) or the stakeholder perception of (Yiran et al., 2012; Ariti et al., 2015). The argument is that whereas remote sensing can provide quantitative data on the magnitude of land cover change, it is the stakeholders who can inform on the driving forces of change and how the changes affect their lives. However, interviews are time-consuming and may be subjective, and for periods further back in time, it is more difficult to gather reliable results (Garedew et al., 2009). As stakeholders base their decisions on their perception of the drivers and impacts of land use and land cover change (Ariti et al., 2015), there is the need to link the observed changes with the driving forces to inform effective and sustainable land use planning (Yiran et al., 2012). Our study provides an example of the analysis of woodland degradation at a local level using a portfolio of methods complementing each other and thus enabling a comprehensive understanding of woodland degradation and the role of charcoal production in specific.

In order to reduce woodland degradation, incentives for landowners to maintain woodland areas should be combined by disseminating technical information and alternative management options, such as beekeeping. This will reduce woodland degradation and dependence on charcoal for sustenance. Extending forestry services to tree planting for charcoal and wood production could reduce the pressure on existing woodlands, as examples of local non-governmental organizations (NGO) such as Katulu have already shown. Moreover, encouraging the use of alternative charcoal production technologies, such as the casamance charcoal kiln and briquetting, can increase the efficiency of charcoal production by reducing the number of trees necessary to produce a given volume of charcoal hence slowing down land cover change (Mekuria et al., 2012). Finally, pressures on woodland can be reduced by increasing agricultural productivity, for instance through the introduction of drought-tolerant crops, manure for fertilization, seasonal forecasts and promotion of soil and water conservation techniques (Recha et al., 2014).

CONCLUSIONS

Landsat imagery analysis, field transects and household interviews provide an in-depth understanding on woodland cover change and degradation. Our study has shown that woodlands are being converted to farmlands and are degraded mainly through charcoal making as result of a host of physical and socio-economic factors. The community is well aware of the woodland degradation and land cover change and relate degradation of the land cover to their perceived worsening livelihoods. To reduce woodland cover loss, our results indicate that there is a need for appropriate policy and technological measures to reduce woodland cover change and degradation. Such measures should target improving the productivity of agriculture to reduce shifting cultivation practice, adaptation to climate change and reducing dependence on charcoal for sustenance in order to address the combined drivers of woodland degradation and loss.

ACKNOWLEDGEMENTS

This study was supported by the Ms Grietje Wille Legacy under the A Sustainable Approach to Livelihood Improvement Project, a joint cooperation between VU University, the Netherlands and SEKU University, Kenya. Additional
support was obtained from the European Research Council under the European Union’s Seventh Framework Programme ERC Grant Agreement no. 311819 (GLOLAND). We thank Dr Julia Schindler of VU University, Dr Kariuki Chege and Dr Peter Njuru both of SEKU for their invaluable advice. We also thank Festus Kakuma for organizing field logistics. The authors declare no conflict of interest.
