Limitations of Noisy Reversible Computation

Dorit Aharonov *  Michael Ben-Or †  Russell Impagliazzo ‡  Noam Nisan §

Abstract

In this paper we study noisy reversible circuits. Noisy computation and reversible computation have been studied separately, and it is known that they are equivalent in power to unrestricted computation. We study the case where both noise and reversibility are combined and show that the combined model is weaker than unrestricted computation.

We consider the model of reversible computation with noise, where the value of each wire in the circuit is flipped with some fixed probability $1/2 > p > 0$ each time step, and all the inputs to the circuit are present in time 0. We prove that any noisy reversible circuit must have size exponential in its depth in order to compute a function with high probability. This is tight as we show that any (not necessarily reversible or noise-resistant) circuit can be converted into a reversible one that is noise-resistant with a blow up in size which is exponential in the depth. This establishes that noisy reversible computation has the power of the complexity class $\text{NC}^1$.

We extend the upper bound to quantum circuits, and prove that any noisy quantum circuit must have size exponential in its depth in order to compute a function with high probability. This highlights the fact that current error-correction schemes for quantum computation require constant inputs throughout the computation (and not just at time 0), and shows that this is unavoidable. As for the lower bound, we show that quasi-polynomial noisy quantum circuits are at least as powerful as quantum circuits with logarithmic depth (or $\text{QNC}^1$). Making these bounds tight is left open in the quantum case.

1 Introduction

In this paper we study noisy reversible circuits. Noisy computation and reversible computation have been studied separately, and it is known that they are equivalent in power to unrestricted computation. We study the case where both noise and reversibility are combined and show that the combined model is weaker than unrestricted computation.

The model of reversible noisy computation seems natural by itself, especially when viewed as a model of physical computation. It is also motivated by the current surge of interest in noise in quantum computation, which generalize reversible computation. Indeed, we extend our lower bounds to the quantum case.

Reversible Circuits

The subject of reversible computation, was first raised with connection to the question of how much energy is required to perform a computation. In this paper we do not wish to argue about when and
in what ways this reversibility condition is indeed a true requirement, but rather limit ourselves to study models in which this requirement holds. The reader can consult for example Landauer\[11\] and Bennett\[3, 4, 5\] for more discussion.

Our model of reversible computation will be boolean circuits which may use only reversible gates.

**Definition 1** A function \(g : \{0,1\}^k \rightarrow \{0,1\}^k\) is called reversible if it is 1-1 (thus, a permutation). A gate with \(k\) inputs and \(k\) outputs is called reversible if it computes a reversible function.

Our circuits will be composed of reversible gates which belong to some fixed set of gates (our computation basis). As is usual in boolean circuits the exact choice of a base is not important as long as it is finite and “universal”. An example of a reversible gate which, by itself, is a universal family is the 3-input, 3-output Toffoli gate. In order to keep reversibility, we do not allow wires in the circuit to “split”, i.e. the fanout of each output wire (or input bit) in the circuit is always 1. It follows that a reversible circuit has \(N\) inputs and \(N\) outputs, for some \(N\), and that it computes a reversible function.

In order to compute non-reversible functions by reversible circuits we apply the following convention.

**Definition 2** We say that a reversible function \(F : \{0,1\}^N \rightarrow \{0,1\}^N\) implements a boolean function \(f : \{0,1\}^n \rightarrow \{0,1\}\) if for every \(x \in \{0,1\}^n\), the first output bit of \(F(x\bar{0})\) is \(f(x)\). Here \(\bar{0}\) means padding \(x\) by \(N-n\) 0-bits in order to get an \(N\)-bit input for \(F\).

The most basic simulation result of general circuits by reversible circuits states:

**Proposition 1** If a boolean function \(f : \{0,1\}^n \rightarrow \{0,1\}\) can be computed by a circuit of size \(s\) and depth \(d\), then it can be implemented by reversible circuits of size \(O(s)\) and depth \(O(d)\).

More advanced simulation results are also known, e.g. that the output on input \(x\bar{0}\) can be forced to be \(x \circ f(x) \circ \bar{0}\), and not just an arbitrary string starting with \(f(x)\).

Noisy Circuits

Normal boolean circuits are very sensitive to “hardware failures”: if even a single gate or single wire malfunctions then the computation may be completely wrong. If one worries about the physical possibility of such failures, then it is desirable to design circuits that are more resilient. Much work has been done on this topic, starting from Von-Neumann \[13\].

The usual models assume that each gate in the circuit can fail with some fixed probability \(p > 0\), in which case its value is flipped or controlled by an adversary. Most upper bounds (as well as ours) work even for the case of an adversary, while most lower bounds (as well as ours) work even for the simpler case of random flips. The aim is to construct circuits that still compute, with high probability, the desired function, even when they are noisy. The probability of error achieved by the circuit (due to the noise) must be at most some fixed constant \(\epsilon < 1/2\). The exact values of \(p\) and \(\epsilon\) turn out not to matter beyond constant factors as long as \(p\) is less than some threshold \(p_0\) (which depends on the computational basis), and \(\epsilon\) is at least some threshold \(\epsilon_0\) (which depends on \(p\) as well as on the computational basis). We say that such a circuit computes the function in a noise-resistant way. The basic simulation results regarding noisy circuits state that any circuit of size \(s\) and depth \(d\) can be converted into a noise-resistant one of size \(\text{poly}(s)\) and depth \(O(d)\) which computes the same function. (For lower bounds on the blow-up in depth and size see \[?, ?\]).

We will be considering a slightly different model in which the errors (noise) are not on the gates, but rather on the wires. We assume that each wire flips its value (or allows an adversary to control its value) with probability \(p\), each “time unit”. This means that we view the depth of a gate in the circuit as corresponding to the “time” in which this gate has its latest input available (its output will be available one time unit later). A wire that connects an output of gate at depth \(d\) to an input of a gate of depth \(d'\), will thus have \(d' - d\) time units in which its value may be flipped (or controlled by an adversary), with probability \(p\) each time unit. We call such circuits noisy circuits.
This model does seem reasonable as a model of many scenarios of noisy computations. An obvious example is a cellular automata whose state progresses in time, and it does seem that each cell can get corrupted each time unit. We invite the reader to consider her favorite physical computation device and see whether its model of errors agrees with ours. In any case, it is easy to see that this model is equivalent in power to the one with noise on the gates, and thus is as powerful as non-noisy circuits [13].

Noisy Reversible Circuits

The model under study in this paper is the model of reversible circuits, as defined above, when the wires are subject to noise, also as defined above. The combination of these two issues has not been, as far as we know, studied formally before, though it might seem natural that given that all operations are reversible, the effect of noise can not be corrected. Indeed, it turns out that this combination is more problematic, in terms of computation power, than each of the elements alone.

We wish to emphasize that this “problematic” behavior appears only with the combination of the definitions we consider – which we feel are the interesting ones, in many cases. Specifically, it is not difficult to see that each of the following variant definitions of “noisy reversible” circuits turns out to be equivalent in power to normal circuits.

- The noise is on the gates instead of on the wires.
- The noise on each wire is constant instead of being constant per time unit.
- The inputs to the circuit can be connected at an arbitrary “level” of the circuit (corresponding to at an arbitrary time), as opposed to only at “time 0”.
- Constant inputs can be connected at arbitrary levels.
- The reversible circuits may contain 1-to-1 functions with a different number of input and output bits.

We first show that noisy reversible circuits can simulate general ones, although with a price which is exponential in the depth.

**Theorem 1** If a boolean function $f$ can be computed by a circuit of size $s$ and depth $d$, then $f$ can be computed by a reversible noisy circuit of size $O(s \cdot 2^{O(d)})$ and depth $O(d)$.

Our main theorem shows that this exponential blowup in depth is un-avoidable. It turns out that noisy reversible circuits must have size which is exponential in the depth in order to do anything useful.

**Definition 3** We say that a noisy reversible circuit is worthless if on every fixed input, its first output bit takes both values (0 and 1) with probability of at least $49/100$ each.

This means that a worthless circuit simply outputs random noise on its first output bit, whatever the input is.

**Theorem 2** For any noisy reversible circuit of size $s$ and depth $d$ which is not worthless, $s = 2^{\Omega(d)}$.

This give a full characterization of polynomial size noisy reversible circuits.

**Corollary 1** Polynomial size noisy reversible circuits have exactly the power of (non-uniform) $NC^1$.

Note that for the lower bounds we do not assume anything on the fan-in of the gates: In fact, the lower bound still hold even if the gates may operate on all the qubits together.
We extend the upper bound, and a weaker version of the lower bound, to quantum circuits, which are the quantum generalization of reversible circuits. We will be using the model of quantum circuits with mixed states, suggested in [2].

The computation is performed by letting a system of $n$ quantum bits, or “qubits”, develop in time. The state of these $n$ qubits is a vector in the complex Hilbert Space $\mathcal{H}_2^n$, generated by the vectors $|0\rangle, |1\rangle, \ldots |2^{n-1}\rangle$, where the numbers $i$ are written in binary representation. This vector space is viewed as a tensor product of $n$ copies of $\mathcal{H}_2$, each corresponding to one of the qubits. The initial state is one of the basic state which corresponds to the input string. This state develops in time according to the gates in the circuit. A quantum gate of order $k$ is a unitary matrix operating in the Hilbert space $\mathcal{H}_2^k$ of $k$ qubits. Our circuits will be composed of quantum gates which belong to some fixed set of gates (our computation basis). As is usual in boolean circuits the exact choice of a base is not important as long as it is finite and “universal”[6, 7]. Keeping the number of qubits constant in time, we do not allow wires in the circuit to “split”, i.e. the fanout of each output wire (or input bit) in the circuit is always 1. It follows that a quantum circuit has $N$ inputs and $N$ outputs, for some $N$. The function that the quantum circuit computes is defined as the result of a “measurement” of the first qubit: i.e. some kind of projection of the final state on a subspace of $\mathcal{H}_n^2$. In the model of quantum circuits with mixed states, we allow the $n$ qubits to be in some probability distribution over vectors in the Hilbert space, and such a general (mixed) state is best described by the physical notion of density matrices.

Noisy Quantum Circuits

As in the classical case, we consider the model of noise on the wires. We assume that each wire (qubit) allows an adversary to control its “value” with probability $p$, each “time unit”. The definition of Quantum noise is more subtle than that of classical noise since the “value” of a qubit is not always defined. Instead, what we mean by “controlling the qubit” is the following operation: An arbitrary operation on the “controlled” qubit and the state of the environment, represented by $m$ qubits in some arbitrary state, is applied, after which the state of the environment is averaged upon, to give the (reduced) density matrix to the $n$ qubits of the circuit. This type of damage on a qubit occurs with probability $p$ each time step for each qubit. The computation is composed alternately of noise steps and computation steps. We call such quantum circuits noisy quantum circuits.

We first show the quantum analog of theorem 1, i.e. that noisy quantum circuits must have size which is exponential in the depth in order to do anything useful.

**Theorem 3** For any noisy quantum circuit of size $s$ and depth $d$ which is not worthless, $s = 2^{\Omega(d)}$.

Where, as for reversible circuits, we say that a noisy quantum circuit is worthless if on every fixed input, its first output bit takes both values (0 and 1) with probability of at least $49/100$ each.

We next give a lower bound on the power of noisy quantum circuits: We show that noisy quantum circuits can simulate general quantum circuits, with an exponential cost.

**Theorem 4** If a boolean function $f$ can be computed by a quantum circuit of size $s$ and depth $d$, then $f$ can be computed by a noisy quantum circuit of size $O(s \cdot \text{polylog}(s)) \cdot 2^{O(d \cdot \text{polylog}(d))}$ and depth $O(d \cdot \text{polylog}(d))$.

This gives a characterization of polynomial size noisy quantum circuits.

**Corollary 2** Polynomial size noisy quantum circuits are not stronger than quantum circuits with $O(\log(n))$ depth (The class $\text{QNC}^1$). On the other hand, Quasi polynomial noisy quantum circuits can compute any function in $\text{QNC}^1$. 

4
For the lower bound we use the results in [3], in which, using noisy quantum circuits which allows the qubit to be initialized at different times, it is shown how to make the circuit noise-resistant with polylogarithmic blow-up in the depth. The reason for the fact that in the quantum case the bounds are not tight, is due to the fact that not as in classical circuits [3], it is yet unknown if quantum noise resistance can be achieved with constant blow-up in the depth.

We emphasize again, that these results is very specific to the model we defined, and as in the case of noisy reversible (classical) circuits, a slight change in the definitions changes dramatically the complexity power, and variant definitions of “noisy quantum circuits” turn out to be equivalent in power to normal quantum circuits, due to the results in [4, 10].

2 Noisy reversible circuits - The Upper Bound

In this section we prove the upper bound, meaning that a noisy reversible circuit can simulate any circuit with exponential cost.

Theorem 5 If a boolean function \( f \) can be computed by a boolean circuit of size \( s \) and depth \( d \), then \( f \) can be computed by a noisy reversible circuit of size \( O(s \cdot 2^{O(d)}) \) and depth \( O(d) \).

Proof: By [3], we can convert the circuit that computes \( f \) to a reversible circuit, \( R \), which has linear depth and polynomial size. We now want to convert \( R \) to \( C \), a noise-resistant reversible circuit which computes \( f \) with high probability. Note that the majority function can be implemented reversibility, by a three bit to three bit gate, of which the first output is the majority of the three inputs. Also, this reversible function on three bits can be implemented by a constant number of gates from the universal set being used, where these gates will operate on the three bits plus a constant number of extra bits, which will all be output in the state they where input. To construct \( C \), replace each bit in \( R \) by \( 3^d \) bits. Each time step we will limit the computation to a third of the bits, which will be “good”. In the \( i \)’th time step we will operate on \( 3^{d-i} \) good bits. This is done as follows: A gate in the \( i \)’th time step in \( R \), is transformed in \( C \) to \( 3^{d-i} \) copies of the same gate, applied bitwise on the \( 3^{d-i} \) good bits. We then divide these bits to triples, apply reversible majority gates on each triple, and limit ourselves to the \( 3^{d-i-1} \) results of these gates, which will be the good bits, on which we operate bitwise the next time step in \( R \), and so on. The claim is that if \( p \) is small enough, the probability for “good” bit at time step \( i \) to err is less than \( p \). The proof is by induction on \( i \): Let the input bits for the \( i \)’th step have error with probability \( \leq p \). Another noise step makes this probability \( \leq 2p \). After the computation step, if the fan-in of the gates is \( \leq k \), than the error probability for each output is \( \leq 2kp \). After another noise step, the error probability is \( \leq (2k + 1)p \). Now apply the majority gate. Note that the error probabilities for each one of the inputs to the majority gates are independent. Hence the error probability for the result of the majority gate is less than \( 3((2k + 1)p)^2 + ((2k + 1)p)^3 \), which is \( \leq 3 \) if \( p \) is smaller than some constant threshold.

3 Noisy Reversible Circuits - The Lower Bound

In this section we prove the lower bound, meaning that after \( O(\log(n)) \) steps of computation there is exponentially small amount of information in the system. We first show that each step of faults, reduces the information in the system by a constant factor which depends only on the fault probability.

Lemma 1 Let \( X \) be a string of \( n \) bits, which is a random variable. Let \( Y \) be the string of \( n \) bits generated from \( X \) by flipping each bit with independent probability \( p \). Then \( I(Y) \leq (1 - 2p)^2 I(X) \), where \( I \) is the Shannon information.

Proof: Let us first prove this for \( n = 1 \). Let \( \alpha, \beta \) be the probability that the bit \( X, Y \) be 1, respectively. Let \( \alpha = 1/2 + \delta/2 \),

\[
\beta = (1 - p)\alpha + p(1 - \alpha) = 1/2 + \delta p/2
\]
where $\rho = 1 - 2p, |\rho| \leq 1$. Then $I(X), I(Y)$ are functions of $\delta$ and $\rho$.

$$I(X) = 1 + p_0 \log(p_0) + p_1 \log(p_1) = K(\delta) = ((1 + \delta) \log(1 + \delta) + (1 - \delta) \log(1 - \delta))/2.$$ Developing $K(\delta)$ to a power series we get

$$K(\delta) = (1/\ln(2)) \sum_{k=1}^{\infty} (\delta)^{2k} /[2k(2k - 1)]$$

converging for all $0 \leq \delta \leq 1$. Therefore

$$I(Y) = K(\delta \rho) = (1/\ln(2)) \sum_{k=1}^{\infty} (\delta \rho)^{2k} /[2k(2k - 1)]$$

$$\leq (1/\ln(2)) \rho^2 \sum_{k=1}^{\infty} \delta^{2k} /[2k(2k - 1)] = \rho^2 K(\delta) = \rho^2 I(X)$$

proving that $I(Y) \leq (1 - 2p)^2 I(X)$. We now use this result to prove for general $n$. Let us write the strings $X, Y$ as $X_1, X_2, ..., X_n$ and $Y_1, Y_2, ..., Y_n$, where $X_i$ and $Y_i$ are random variables that get the value 0 or 1.

$$I(Y) = \sum_{i=1}^{n} I(Y_i|Y_{i+1}, ..., Y_n) \leq \sum_{i=1}^{n} I(Y_i|X_{i+1}, ..., X_n),$$

where we used the fact that $I(A|C) \leq I(A|B)$ where $A, B, C$ are random variables, and $C$ is a function of $B$, where the function might also be a random variable, independent of $A$ and $B$. Using the following known formula: $I(A|B) = \sum_b \Pr(B = b) I(A|b)$, we can write the last term as

$$I(Y) \leq \sum_{i=1}^{n} \sum_{x_{i+1}, ..., x_n} \Pr(X_{i+1} = x_{i+1}, ..., X_n = x_n) I(Y_i|x_{i+1}, ..., x_n) \leq$$

$$\sum_{i=1}^{n} \sum_{x_{i+1}, ..., x_n} \Pr(X_{i+1} = x_{i+1}, ..., X_n = x_n)(1 - 2p)^2 I(X_i|x_{i+1}, ..., x_n) = (1 - 2p)^2 I(X),$$

where we have used the proof for one variable.

We can now prove the main theorem:

**Theorem:** For any noisy reversible circuit of size $s$ and depth $d$ which is not worthless, $s = 2^{\Omega(d)}$.

**Proof:** We first note that since each level of computation is reversible, the entropy does not change due to the computation step, and since the number of bits is constant, the information does not change too during a computation step. We start with information $n$, and it reduces with rate which is exponential in the number of noise steps: After $m$ steps the information in the system is less than $(1 - 2p)^{2m} n$, by lemma. When $m = O(\log(n))$ the information is polynomially small. The information on any bit is smaller than the information on all the bits.

### 4 Quantum Computation

In this section we recall the definitions of quantum circuits with mixed states, quantum noise, and quantum entropy.
4.0.1 Pure states

We deal with systems of n two-state quantum particles, or “qubits”. The pure state of such a system is a unit vector, denoted $|\alpha\rangle$, in the Hilbert space $\mathbb{C}^2$, i.e. a $2^n$ dimensional complex space. We view $\mathbb{C}^2$ as a tensor product of n two dimensional spaces, each corresponding to a qubit: $\mathbb{C}^{2^n} = \mathbb{C}^2 \otimes \cdots \otimes \mathbb{C}^2$. As a basis for $\mathbb{C}^2$, we use the $2^n$ orthogonal basic states: $|i\rangle = |i_1\rangle \otimes |i_2\rangle \cdots \otimes |i_n\rangle$, $0 \leq i < 2^n$, where $i$ is in binary representation, and each $i_j$ gets 0 or 1. Such a state corresponds to the j’th qubit being in the state $|i_j\rangle$. A pure state $|\alpha\rangle \in \mathbb{C}^{2^n}$ is a superposition of the basic states: $|\alpha\rangle = \sum_{i=1}^{2^n} c_i|i\rangle$, with $\sum_{i=1}^{2^n} |c_i|^2 = 1$. $|\alpha\rangle$ corresponds to the vector $v_\alpha = (c_1, c_2, ..., c_{2^n})$. $v_\alpha^\dagger$, the complex conjugate of $v_\alpha$, is denoted $\langle \alpha |$. The inner product between $|\alpha\rangle$ and $|\beta\rangle$ is $\langle \alpha | \beta \rangle = (v_\alpha, v_\beta^\dagger)$. The matrix $v_\alpha^\dagger v_\beta$ is denoted as $|\alpha\rangle \langle \beta |$. An isolated system of n qubits develops in time by a unitary matrix $A$ of size $2^n \times 2^n$: $|\alpha(t_2)\rangle = U|\alpha(t_1)\rangle$. A quantum system in $\mathbb{C}^{2^n}$ can be observed by measuring the system. An important measurement is a basic measurement of a qubit $q$, of which the possible outcomes are 0, 1. For the state $|\alpha\rangle = \sum_{i=1}^{2^n} c_i|i\rangle$, the probability for outcome 0 is $p_0 = \sum_{i,i_0=0} |c_i|^2$ and the state of the system will collapse to $|\beta\rangle = \frac{1}{p_\beta} \sum_{i,i_0=0} c_i|i\rangle$, (the same for 1). In general, an observable $O$ over $\mathbb{C}^{2^n}$ is an hermitian$^1$ matrix, of size $2^n \times 2^n$. To apply a measurement of $O$ on a pure state $|\alpha\rangle \in \mathbb{C}^{2^n}$, write $|\alpha\rangle$ uniquely as a superposition of unit eigenvectors of $O$: $|\alpha\rangle = \sum_i c_i|\alpha_i\rangle$, where $|\alpha_i\rangle$ have different eigenvalues. With probability $|c_i|^2$ the measurement’s outcome will be the eigenvalue of $|\alpha_i\rangle$, and the state will collapse to $|\alpha_i\rangle$. A unitary operation $U$ on k qubits can be applied on n qubits, $n \geq k$, by taking the extension $\hat{U}$ of $U$, i.e. the tensor product of $U$ with an identity matrix on the other qubits. The same applies for an observable $O$ to give $\hat{O}$.

4.0.2 Mixed states

A system which is not ideally isolated from it’s environment is described by a mixed state. There are two equivalent descriptions of mixed states: mixtures and density matrices. We use density matrices in this paper. A system in the mixture $\{\alpha\} = \{p_\alpha, |\alpha_i\rangle\}$ is with probability $p_\alpha$ in the pure state $|\alpha_i\rangle$. The rules of development in time and measurements for mixtures are obtained by applying classical probability to the rules for pure states. A density matrix $\rho$ on $\mathbb{C}^{2^n}$ is an hermitian$^1$ positive semi definite complex matrix of dimensions $2^n \times 2^n$, with $tr(\rho) = 1$. A pure state $|\alpha\rangle = \sum_i c_i|i\rangle$ is associated the density matrix $\rho(\alpha) = |\alpha\rangle \langle \alpha |$ i.e. $\rho(\alpha)(i,j) = c_i^* c_j$. A mixture $\{\alpha\} = \{p_\alpha, |\alpha_i\rangle\}$, is associated the density matrix : $\rho(\alpha) = \sum_i p_i \rho(\alpha_i)$. The operations on a density matrix are defined such that the correspondence to mixtures is preserved. If a unitary matrix $U$ transforms the mixture $\{\alpha\} = \{p_\alpha, |\alpha_i\rangle\}$ to $\{\beta\} = \{p_\beta, U|\alpha_i\rangle\}$, then $\rho(\beta) = \sum_i p_i U^\dagger |\alpha_i\rangle \langle \alpha_i | U = U \rho(\alpha) U^\dagger$. Let $\rho$ be written in a basis of eigenvectors $v_i$ of an observable $O$. A measurement of $\rho$ on gives, the outcome $\lambda$ with the probability which is the sum of the diagonal terms of $\rho$, which relate to the eigenvalue $\lambda$: $pr(\lambda) = \sum_{i=1}^{2^n} \rho_{c_i} \delta(\lambda_i = \lambda)$. conditioned that the outcome is the eigenvalue $\lambda$, the resulting density matrix is $O_\lambda \circ (\rho)$, which we get by first putting to zero all rows and columns in $\rho$, which relate to eigenvalues different from $\lambda$, and then renormalizing this matrix to trace one. Without conditioning on the outcome the resulting density matrix will be $O \circ (\rho) = \sum_k Pr(\lambda_k) O_{\lambda_k} \circ (\rho)$. which differs from $\rho$ only in that the entries in $\rho$ which connected between different eigenvalues are put to zero. Given a density matrix $\rho$ of n qubits, the reduced density matrix of a subsystem $A$, of, say, m qubits is defined as an average over the states of the other qubits: $\rho_{|A}(i,j) = \sum_{k=1}^{2^{n-m}} \rho(ik,jk)$.

4.1 Quantum circuits with mixed states

A quantum unitary gate of order $k$ is a complex unitary matrix of size $2^k \times 2^k$. A density matrix $\rho$ will transform by the gate to $g \circ \rho = \hat{U} \rho \hat{U}^\dagger$, where $\hat{U}$ is the extension of $U$. A measurement gate of

\footnotesize
\begin{itemize}
    \item A Hilbert space is a vector space with an inner product
    \item Unitary matrices preserve the norm of any vector and satisfy the condition $U^{-1} = U^\dagger$
    \item An hermitian matrix $H$ satisfies $H = H^\dagger$
\end{itemize}

\normalsize
order $k$ is a complex hermitian matrix of size $2^k \times 2^k$. A density matrix $\rho$ will transform by the gate to $g \circ \rho = \hat{O} \circ (\rho)$. A Quantum circuit is a directed acyclic graph with $n$ inputs and $n$ outputs. Each node $v$ in the graph is labeled by a quantum gate $g_v$. The in-degree and out-degree of $v$ are equal to the order of $g_v$. Some of the outputs are labeled “result” to indicate that these are the qubits that will give the output of the circuit. The wires in the circuit correspond to qubits. An initial density matrix $\rho$ transforms by a circuit $Q$ to a final density matrix $Q \circ \rho = g_t \circ \ldots \circ g_2 \circ g_1 \circ \rho$, where the gates $g_t, \ldots, g_1$ are applied in a topological order. For an input string $i$, the initial density matrix is $\rho |i\rangle$. The output of the circuit is the outcome of applying basic measurements of the result qubits, on the final density matrix $Q \circ \rho |i\rangle$. Since the outcomes of measurements are random, the function that the circuit computes is a probabilistic function, i.e. for input $i$ it outputs strings according to a distribution which depends on $i$.

4.2 Noisy Quantum Circuits

As any physical system, a quantum system is subjected to noise. The process of errors depends on time, so the quantum circuit will be divided to levels, or time steps. In this model, (as in [14] but not as in [1]) all qubits are present at time 0. The model of noise we use for noisy quantum circuits is a single qubit noise, in which a qubit is damaged with probability $1/2 > p > 0$ each time step. The damage operates as follows: A unitary operation operates on the qubit and a state of the environment (The environment can be represented by $m$ qubits in some state). This operation results in a density matrix of the $n$ qubits of the system and the environment. We reduce this density matrix to the $n$ qubits of the circuit to get the new density matrix after the damage. The density matrix of the circuit develops by applying alternately the computation step and this probabilistic process of noise. The function computed by the noisy quantum circuit is naturally the average over the outputs, on the probabilistic process of noise.

4.3 Quantum Entropy

In this subsection we give some background about the notion of quantum entropy and it’s relation to Shannon information. All definitions and lemmas can be found in the book of Asher Peres[12].

**Definition 1** The (von Neumann) entropy of a density matrix $\rho$ is defined to be $S(\rho) = -\text{Tr}(\rho \log_2(\rho))$.

**Definition 2** The information in a density matrix $\rho$ of $n$ qubits is defined to be $I(\rho) = n - S(\rho)$.

The Shannon entropy, $H$, in the distribution over the results of any measurement on $\rho$ is larger then the Von-Neumann entropy in $\rho$. This means that one can not extract more Shannon information from $\rho$ than the Von Neumann information.

**Lemma 2** Let $O$ be an observable of $n$ qubits, $\rho$ a density matrix of $n$ qubits. Let $f$ be the distribution which $\rho$ induces on the eigenvalues of $O$. Then $H(f) \geq S(\rho)$.

As the Shannon entropy, the Von-Neumann entropy is concave:

**Lemma 3** Let $\rho_i$ be density matrices of the same number of qubits. Let $p_i$ be some distribution on these matrices. $S(\sum_i p_i \rho_i) \geq \sum_i p_i S(\rho_i)$.

The Shannon entropy of two independent variables is just the sum of the entropies of each one. The Quantum analog is that the Von-Neumann entropy in a system which consists of non-entangled subsystems is just the sum of the entropies:

**Lemma 4** $S(\rho_1) + S(\rho_2) = S(\rho_1 \otimes \rho_2)$.

One can define a relative Von-Neumann entropy:
Definition 3 Let $\rho_1, \rho_2$ be two density matrices of the same number of qubits. The relative entropy of $\rho_1$ with respect to $\rho_2$ is defined as $S(\rho_1 | \rho_2) = \text{Tr}[\rho_2 (\log_2 \rho_2 - \log_2 \rho_1)]$.

The relative entropy is a non-negative quantity:

Lemma 5 Let $\rho_1, \rho_2$ be two density matrices of the same number of qubits. The relative entropy of $\rho_1$ with respect to $\rho_2$ is non-negative: $S(\rho_1 | \rho_2) \geq 0$.

5 The Quantum upper Bound

In this section we prove the upper bound for the case of noisy quantum circuits: a noisy quantum circuit can simulate any quantum circuit with exponential cost.

Theorem 4: If a boolean function $f$ can be computed by a quantum circuit of size $s$ and depth $d$, then $f$ can be computed by a noisy quantum circuit of size $O(s \cdot \text{polylog}(s)) \cdot 2^{O(d \cdot \text{polylog}(d))}$ and depth $O(d \cdot \text{polylog}(d))$.

Proof: In [1] it is shown that any quantum circuit $Q$, with depth $d$ and size $s$, can be simulated by a noisy quantum circuit $\tilde{Q}$, with depth polylogarithmic in $d$ and size polylogarithmic in $s$, where a different model of noisy quantum circuit is used: qubits are allowed to be initialized at any time during the computation. To adapt the proof to our model, in which all qubits are present at time 0, it will suffice to show that there exists a noisy quantum circuit, $A_t$, with depth $t$ operating on $3^t$ qubits, such that if the error probability is $p$, for an input string of all zeroes, at time $t$ the first qubit is in the state $|0\rangle$ with probability $\geq (1 - p)$. If such $A_t$ exists, than for each qubit, $q$, which is input to $Q$ at time $t$, we simply add $3^t - 1$ qubits to the circuit, and together with $q$ they will be initialized at $t = 0$ to be $|0\rangle$. On these $3^t$ qubits we will operate the sequence of gates $A_t$, and the first qubit will play the role of $q$ after time $t$. The new circuit is a noisy quantum circuit for which all qubits are initialized at time 0, it’s size is $O(s \cdot \text{polylog}(s)) \cdot 2^{O(d \cdot \text{polylog}(d))}$ and depth $O(d \cdot \text{polylog}(d))$.

$A_t$ is constructed as follows: We begin with $3^t$ qubits in the state $|0\rangle$. These qubits can be divided to triples of qubits. We apply the following “majority” quantum gate, on each triple:

\[
\begin{align*}
|000\rangle &\rightarrow |000\rangle, & |100\rangle &\rightarrow |011\rangle \\
|001\rangle &\rightarrow |001\rangle, & |101\rangle &\rightarrow |101\rangle \\
|010\rangle &\rightarrow |010\rangle, & |110\rangle &\rightarrow |110\rangle \\
|011\rangle &\rightarrow |100\rangle, & |111\rangle &\rightarrow |111\rangle.
\end{align*}
\]

The first qubit of each triple carries now the result of the majority. (Note that the function of majority works here, in the quantum case, because we only need to deal with non-entangled states: the zero $|0\rangle$ state. The majority gate is not a good method to pick the majority out of three general pure states.) All these $3^{t-1}$ result qubits can now be divided also to triples, and we apply majority gates on these triples, and so on, until time $t$. We claim that the error probability of the result qubits of time step $i \leq t$ is $\leq p$, if $p$ is smaller than some threshold. Let us prove this by induction on $i$. If each qubit in the $i$'th time step has error probability $\leq p$, then after one noise step it’s error probability is $\leq 2p$. The majority gate is applied on qubits with independent error probabilities. Thus the probability for the majority result to err is less than $3(2p)^2 + (2p)^3$. This probability is smaller than $p$ if $p$ is small enough.

6 The Quantum Lower Bound

We prove that in a noisy quantum circuit the information decreases exponentially in the number of time steps, in the presence of the following type of quantum noise, where a qubit that undergoes a
fault is replaced by a qubit in one of the basic states, which is chosen randomly. Such a qubit carries no information. We first show that a noise step causes the information in the circuit to decrease at least by a constant factor \((1 - p)\), and then show that quantum gates can only decrease the information in the system. This is true even for the more general model of quantum non-reversible circuits, where measurement gates are allowed.

Let us first show that quantum gates can only reduce information:

**Lemma 6** Let \( g \) be a quantum gate, \( \rho \) a density matrix. \( I(g \circ \rho) \leq I(\rho) \).

**Proof:** For a unitary gate, which is reversible, \( I(\rho) = I(g \circ \rho) \). The proof for the case of a measurement gate is given in the appendix.

In order to show that during a noise step the information decreases by a factor, we need the following lemma, (which is the quantum analog of a theorem proved in [1]): The average information in \( k \) qubits chosen randomly out of \( n \) qubits, is smaller than \( \frac{k}{n} \) the information in all the \( n \) qubits.

**Lemma 7** Let \( \rho \) be a density matrix of \( n \) qubits, and let \( k < n \). Then \( \sum_{k=1}^{n} \frac{1}{n} I(A_k) \leq \frac{k}{n} I(\rho) \).

We can now prove that for a specific type of quantum noise, that in which qubit is replaced with probability \( p \) by a qubit in a random state, the information in the quantum circuit decreases by a factor of \((1 - p)\) after each noise step:

**Lemma 8** Let \( \rho \) be a density matrix of \( n \) qubits. Let each qubit in \( \rho \) be replaced with independent probability \( p \) by a qubit in the density matrix \( \rho_R = \frac{1}{2}(|0\rangle\langle 0| + |1\rangle\langle 1|) \), to give the density matrix \( \sigma \). Then \( I(\sigma) \leq (1 - p)I(\rho) \).

**Proof:**

Let us write \( \sigma = \sum_{k=1}^{n} \sum_{A_k} p^{n-k}(1 - p)^k \rho|A_k \rangle \langle A_k| \otimes \rho_R^{n-k} \), where the sum over \( A_k \) is a sum over all subsets of \( k \) qubits, and the power on the density matrices means taking \( n - k \) times the tensor product of \( \rho_R \). This presents the resulting density matrix as a probability distribution over all possible cases where the faults could have occurred, with the correct probabilities. By the concavity of the entropy we have: \( I(\sigma) \leq \sum_{k=1}^{n} p^{n-k}(1 - p)^k \sum_{A_k} I(\rho|A_k \rangle + (n - k)I(\rho_R) \), where we have used lemma [1]. Since \( I(\rho_R) = 0 \), we have that

\[
I(\sigma) \leq \sum_{k=0}^{n} p^{n-k}(1 - p)^k \sum_{A_k} I(\rho|A_k \rangle).
\]

Using lemma [1], we get \( I(\sigma) \leq \sum_{k=1}^{n} p^{n-k}(1 - p)^k \frac{k}{n} I(\rho) = (1 - p)I(\rho) \).

We can now prove the lower bound on noisy quantum circuits:

**Theorem 3** For any noisy quantum circuit of size \( s \) and depth \( d \) which is not worthless, \( s = 2^\Omega(d) \).

**Proof:** Using lemmas [3] and [8] we can show by induction on \( t \) that after \( t \) time steps, the information in the system \( I(\rho) \leq (1 - p)^t s \), so the information in the final density matrix is \( \leq (1 - p)^d s \). The classical information in the probability distribution which we get when measuring the result qubits in \( \rho \) is smaller than \( I(\rho) \), due to lemma [3] and the fact that the basic measurements of the \( r \) result qubits can be replaced by one observable on the result qubits, with each possible string \( |i\rangle \) as an eigenvector with eigenvalue \( i \).

7 Open Question

We have shown that the power of noisy reversible circuit is as the complexity class \( NC_1 \). Is the power of noisy quantum circuit exactly that of the quantum analog complexity class, \( QNC_1 \)? Making the lower bound tight connects to the following open question: Can noisy quantum circuits be made noise resistant with only a constant blow-up in depth?

8 Appendix-Quantum Entropy lemmas

In this appendix we give the proofs of lemmas regarding quantum entropy. All the proofs, except the last one which is a new result as far as we know, are taken from [12].

Lemma 2: Let $O$ be an observable of $n$ qubits, $\rho$ a density matrix of $n$ qubits. Let $f$ be the distribution which $\rho$ induces on the eigenvalues of $O$. Then $H(f) \geq S(\rho)$.

Proof: Let $\{v_i\}$ be the eigenvectors of $\rho$, with $P_i$ there eigenvalues. $S(\rho) = -\sum_i P_i \log(p_i)$. The probability to get an eigenvalue $\lambda_j$ measuring $\rho$ is $Q_j = \sum_k P_k G_{k,j}$, where $G_{k,j}$ is the probability to get $\lambda_j$ when measuring $v_k$. So $S(f) = -\sum_j Q_j \log(Q_j)$. $S(f) - S(\rho) = \sum_i P_i \log(p_i) - \sum_j Q_j \log(Q_j) = \sum_i P_i (\log(p_i) - \sum_j G_{i,j} \log(Q_j)) = \sum_{i,j} P_i G_{i,j} \log(P_i/Q_j)$. Where we have used $\sum_j G_{i,j} = 1$. Now $\log x \geq 1 - \frac{1}{x}$, to give that $S(f) - S(\rho) \geq \sum_{i,j} P_i G_{i,j} (1 - Q_i/P_j) = 0$.

Lemma 3: Let $\rho^i$ be density matrices of the same number of qubits. Let $p^i$ be some distribution on these matrices. $S(\sum_i p^i \rho^i) \geq \sum_i p^i S(\rho^i)$.

Proof: Let us interprate the diagonal terms in a density matrix $\rho$ as a classical probability distribution $D$. We have that in any basis, $H(D) \leq S(\rho)$, where the equality is achieved if and only if the $\rho$ is
written in the basis which diagonalized it. Let us write all matrices in the basis which diagonalizes the matrix \( \rho = \sum p_i \rho_i \), and let the diagonal terms of \( \rho \) be the distribution \( D \) and the diagonal terms in \( \rho_i \) be the distributions \( D_i \), respectively. We than have \( \log(D) = H(D) = H(\sum p_i D_i) \), where the sum is in each coordinate, and by the concavity of classical entropy, we have that \( H(\sum p_i D_i) \leq \sum p_i H(D_i) \), but since \( H(D_i) \leq S(\rho_i) \) it closes the proof.

**Lemma 3:** \( S(\rho_1) + S(\rho_2) = S(\rho_1 \otimes \rho_2) \).

**Proof:** If \( \{ \lambda_1^i \}, \{ \lambda_2^i \} \) are the sets of eigenvalues of \( \rho_1, \rho_2 \) respectively, the eigenvalues of \( \rho_1 \otimes \rho_2 \) are just \( \{ \lambda_1^i \lambda_2^j \} \), and the entropy is \( S(\rho_1 \otimes \rho_2) = -\sum_{i,j} \lambda_1^i \lambda_2^j \log(\lambda_1^i \lambda_2^j) = S(\rho_1) + S(\rho_2) \).

**Lemma 6:** Let \( \rho \) be a density matrix corresponding eigenvalues, respectively. We can write \( \log(\rho) = \sum \lambda_k \log(\lambda_k) \) in this basis \( \rho \) is diagonal. The diagonal elements of \( \log(\rho_2) \) in this basis are: \( \log(\rho_2)_{m,m} = \sum_n \log(\lambda_n^2) |\langle m|v_n^2|v_n^1\rangle|^2 \), where we have used \( \sum_n |\langle m|v_n^2|v_n^1\rangle|^2 = 1 \). Since \( \log(x) \geq 1 - \frac{1}{x} \), \( S(\rho_1 | \rho_2) \geq \sum_{m,n} \lambda^1_m \sum_n |\langle m|v_n^2|v_n^1\rangle|^2 (1 - \frac{\lambda^2_n}{\lambda^2_m}) = \sum_{m,n} \lambda^1_m \sum_n |\langle m|v_n^2|v_n^1\rangle|^2 - \sum_n \lambda^1_i \sum_{m} |\langle m|v_n^2|v_n^1\rangle|^2 = 0 \). Let us prove another fact which will be needed.

**Lemma 9** Let \( \rho_1 \) be a reduced density matrix of \( \rho \) to a subsystem \( A \). Then \( -Tr(\log(\rho_1 \otimes \rho)) = -Tr(\rho_1 \log(\rho_1)) = S(\rho_1) \).

**Proof:** If \( \rho \) is diagonal. In this basis \( \log(\rho)_{m,m} = \log(|\langle m|\rangle)_{i,i} \), where the first index (i or j) indicates qubits in \( A \), and the second index indicates the qubits which we disregard and trace over. \( -Tr(\log(\rho_1 \otimes \rho)) = -\sum_{i,j} \rho_{i,j} \log(\rho_{i,j}) = -\sum \rho_{i,i} \log(\rho_{i,i}) = S(\rho_1) \), where we have used the fact that \( \rho_1 \) is a reduced density matrix which satisfies \( (\rho_1)_{i,j} = \sum_n (\rho)_{i,n} \).

**Lemma 4:** Let \( g \) be a quantum gate, \( \rho \) a density matrix. \( I(g \circ \rho) \leq I(\rho) \).

**Proof:** The entropy is invariant under unitary transformation, since unitary transformations change the eigenvectors, but does not change the set of eigenvalues which is what determines the entropy of the density matrix. Therefore the information does not change if \( g \) is unitary. If \( g \) is a measurement gate, let us write \( g \circ \rho \) in a basis of eigenvectors of the extension of the observable \( g \), in which \( g \circ \rho \) is diagonalizes. By lemma 3, the relative entropy of \( g \circ \rho \) with respect to \( \rho \) is non negative. Writing the relative entropy in the basis of eigenvectors: \( 0 \leq S(g \circ \rho | \rho) = Tr(\rho \log(\rho) - \log(\rho g \circ \rho)) = -S(\rho) - \sum m_n \rho_{m,m} \log(\rho g \circ \rho)_{m,m} = -S(\rho) + S(g \circ \rho) \), where the last equality is due to the fact that in this basis \( \rho_{m,m} = (g \circ \rho)_{m,m} \). Hence \( n - S(g \circ \rho) \leq n - S(\rho) \).

**Lemma 5:** Let \( \rho \) be a density matrix of \( n \) qubits, and let \( k < n \). Then \( \frac{1}{n} \sum_{A_k} I(\rho|A_k) \leq \frac{k}{n} I(\rho) \).

**Proof:** Let \( \rho_1 \) be the tensor product of \( k \left( \begin{array}{c} n \\ k \end{array} \right) \) copies of \( \rho \), and let \( \rho_2 \) be the tensor product of all the possible reduced \( \rho|_{A_k} \), each taken \( n \) copies. \( \rho_1 \) and \( \rho_2 \) are matrices of an equal number of qubits: \( nk \left( \begin{array}{c} n \\ k \end{array} \right) \). Hence we can use the non negativity of the relative entropy (lemma 3), and write
\[ 0 \leq S(\rho_2 | \rho_1) = \text{Tr}(\rho_1 (\log(\rho_1) - \log(\rho_2))) = -S(\rho_1) - \text{Tr}(\rho_1 \log(\Pi_{A_k} (\rho_{A_k})^n)) = -k \binom{n}{k} S(\rho) - \sum_{A_k} \text{Tr}(\rho_1 \log((\rho_{A_k})^n \otimes I^n)), \]

where all products and powers of matrices are understood as tensor products, and using the fact that the logarithm of tensor products can be written as the sum of logarithms. We now observe that \((\rho_{A_k})^n\) is a reduced density matrix of \(\rho_1\) if \(k > 0\). Lemmas 9 and 4 imply that \[ 0 \leq -k \binom{n}{k} S(\rho) + \sum_{A_k} n S(\rho_{A_k}), \]

so for \(k > 0\), \[ \sum_{A_k} I(\rho_{A_k}) \leq \frac{k}{n} \binom{n}{k} I(\rho). \]
