We introduce a systematic approach for the resummation of perturbative series which involve large logarithms not only due to large invariant mass ratios but large rapidities as well. Series of this form can appear in a variety of gauge theory observables. The formalism is utilized to calculate the jet broadening event shape in a systematic fashion to next to leading logarithmic order. An operator definition of the factorized cross section as well as a closed form of the next-to leading log cross section are presented. The result agrees with the data to within errors.

Observables in weakly coupled gauge theories often necessitate perturbative resummations to be under calculational control. This need arises when one performs measurements that are sensitive to infrared scales. By probing distances long compared to the hard scattering scale one introduces large logarithms (logs) that lead to the breakdown of fixed order perturbative series. Resumming the large logs has become standard in QCD [1] and can be accomplished by factorizing the cross section into momentum regions. Factorization makes clear the distinction between logs of various ratios that may be involved in the observable and resummation follows via standard renormalization group techniques.

An elegant formalism for factorization is SCET (Soft-Collinear Effective Theory) [2], which is an effective field theory designed to reproduce the infra-red physics in high energy processes. The formalism not only streamlines factorization proofs [3], but also allows one to systematically include power corrections. The results of this paper will all be couched in terms of this framework.

A generic factorized cross section takes on the form:

\[ \sigma = H \otimes [\Pi_i J_i] \otimes S. \quad (1) \]

The hard function \( H \) is responsible for reproducing the short distance physics with wavelengths of order \( 1/Q \), where \( Q \) is the scale involved in the hard scattering. \( J_i \) and \( S \) are the so-called jet and soft functions containing modes which are highly energetic (collinear) and soft, respectively. Soft modes have small rapidities \((k_+/k_- \sim 1)\) while the rapidities of collinear modes are parametrically larger \((k_+/k_{\perp} \gg 1)\), where \( k_\pm \) are the light cone momenta. The tensor product implies the existence of one or more convolution in momentum space. In canonical situations, the resummation of large logs is accomplished by evolving, via the renormalization group (RG), each factorized component to its natural scale. The natural scales are set by the arguments of the logs. \( H, J \) and \( S \) may contain, for example, logs of \( Q/\mu, m_J/\mu, m_S/\mu \), respectively, where \( m_J \) and \( m_S \) are quantities which probe the invariant masses of the modes composing \( J \) and \( S \).

While there is a large disparity in rapidity between the modes which compose \( S \) and \( J \), the typical invariant mass of the modes need not be distinct. When soft fields have invariant mass parametrically smaller than the collinear modes (in this case the soft mode are called “ultra-soft”) significant simplifications arise. Whether or not there is a distinction in invariant masses, one must always ensure that there is no double counting of modes. That is, loop integrals within a prescribed function \((J \text{ or } S)\) should only account for the relevant mode. In principle this could be accomplished using a cut-off, but this would lead to multiple technical difficulties not the least of which is the need for gauge non-invariant counter-terms. Within the effective field theory formalism using dimensional regularization, this double counting is avoided by the so-called zero-bin procedure [4]. In this methodology one subtracts from each loop integral its value when the integrand is asymptotically expanded around the extraneous region. This procedure not only formally avoids the double counting, but also ensures that all integrals in the theory are well defined. Moreover, the zero bin subtraction, or some equivalent subtraction method, is necessary to preserve factorization [5]. This potential breakdown of factorization occurs as a consequence of the need to regulate “rapidity divergences” (light-cone singularities). These divergences arise schematically from integrals of the form

\[ I_R = \int \frac{dk_+}{k_+}. \quad (2) \]

which are not regulated in dimensional regularization. There are multiple ways of regulating this divergence. A simple way is to introduce a new dimensionful parameter \( \Delta \) via the replacement \( k_+ \rightarrow k_+ + \Delta \) in the denominator. Note that regulating these divergences will break boost invariance along light-cone direction. For any physical observable the final result must be boost invariant and independent of \( \Delta \); this is automatic once zero-bin subtraction is performed and all sectors added. For the case of \( m_J \gg m_S, \Delta \) dependence cancels in each sector after zero bin subtraction, and the boost symmetry is restored in each sector. This will, however, not be the case when \( m_J \sim m_S \), since the soft and collinear modes mix under boosts.

When \( m_J \sim m_S \) the jet axis, defined as the direction of the net momentum of the jet, recoils against the soft emission. In the light-cone co-ordinates, collinear modes scale like \((n \cdot p, \bar{n} \cdot p, p_\perp) \sim Q(1, \lambda^2, \lambda)\) while soft modes...
scale as $Q(\lambda, \lambda, \lambda)$, where $\lambda \ll 1$ and $n^\mu$ is the light-cone direction chosen to perform the factorization. The jet axis is no longer aligned with $n^\mu$, and one should not expect the jet function to be invariant under boosts along $n^\mu$. However, the sum of all sectors will still be invariant. If we were to reanalyze the rapidity divergences discussed previously we would find that the $\Delta$ regulator will cancel after summing over contributions from all sectors (with proper zero-bin subtractions) \cite{srb}. Boost non-invariance in the jet function appears in the form $\log[\Delta]$ a "rapidity log". Resumming these logs using a $\Delta$ regulator, is technically cumbersome much like resummations with a cut-off regulator. Here we introduce a regulator more in the spirit of dimensional regularization that does not factorize in a consistent fashion \cite{scet}. Boost non-invariance of the jet function to be invariant under boosts along $n^\mu$, along the lines of $\nu$ will introduce another arbitrary scale $\nu$ along the lines of $\nu$.

To illustrate this rapidity renormalization group we will consider the specific example of the event shape called jet broadening. Event shapes have played an important role in precision measurements of the strong coupling $\alpha_s$ \cite{ev}. A generalized event shape for event $e^-e^+ \to X$ at center of mass energy $\sqrt{s}$, can be defined \cite{ev2} in terms of a parameter $\alpha$ via

$$e(\alpha) = \sum_{i \in X} \frac{|\vec{p}_{i\perp}|}{\sqrt{s}} e^{-|\eta_i|(1-\alpha)}$$

where $p_{i\perp}$ is the transverse momentum with respect to the thrust axis of the event, and $\eta_i$ is the rapidity of the $i$'th particle. The thrust axis $\hat{t}$ is defined via $\max_{i} \sum_{i \in X} |p_i \cdot \hat{t}|/\sqrt{s}$. Two particularly interesting event shapes are the limits $a = 0, 1$ corresponding to "thrust" and "jet broadening" respectively. The limit $\varepsilon \ll 1$ isolates events composed of back to back jets. In the case of thrust these jets are composed of collinear radiation, and the recoil due to soft (ultra-soft in this case) radiation does not affect the jet axis. While for jet broadening all radiation with parametrically similar transverse momentum can contribute, so that soft radiation of the form $Q(\lambda, \lambda, \lambda)$ recoils the jet off the thrust axis. In both of these cases fixed order perturbation theory will fail when $\varepsilon$ is small. However, as long as $eQ \gg \Lambda_{QCD}$, we expect non-perturbative effects to be suppressed, though large logs of $\varepsilon$ need to be resummed.

The pioneering work on jet broadening resummations \cite{pioneering} utilized the coherent branching formalism \cite{coherent}. It was later stated \cite{later} that the results in \cite{pioneering} neglected terms due to recoil of soft gluons. In this letter we will provide a factorization theorem for jet broadening, whose proof will follow in a subsequent publication \cite{factorize}. The factorization proofs for angularity observables \cite{angular} in \cite{factorize} are known to fail as $a$ approaches 1, since there are growing power corrections in this limit where one approaches jet broadening. The reason for the apparent breakdown of factorization is the fact that in this limit the soft radiation has the same invariant mass as collinear radiation and one must change the power counting accordingly to factorize in a consistent fashion \cite{factorize}.

Hereforth, we set $a = 1$ and $e(1) \equiv e$. In \cite{factorize} prove that the cross section for jet broadening takes the following factorized form

$$\frac{d\sigma}{de} = \sigma_0 H(s) \int dp_{1t} dp_{2t} J_n(Q_+,e_+,p_{1t}) J_n(Q_-,e_-,p_{2t}) S(e_+,p_{1t},p_{2t})$$

where $J_n$ and $S$ are soft Wilson lines. $\hat{\chi}$ is the jet in dimensional regularization. We expect that in order to properly resum all the large logs we will need to run the jet in $\nu$ down to the smaller rapidity scale of the soft function. In a Wilsonian sense we have two distinct cutoffs with which to thin degrees of freedom. There will be one flow in invariant mass and one in rapidity as shown in Fig. [1] This is an inherently Minkowskian procedure.

To illustrate this rapidity renormalization group we will consider the specific example of the event shape called jet broadening. Event shapes have played an important role in precision measurements of the strong coupling $\alpha_s$ \cite{ev}. A generalized event shape for event $e^-e^+ \to X$ at center of mass energy $\sqrt{s}$, can be defined \cite{ev2} in terms of a parameter $\alpha$ via

$$e(\alpha) = \sum_{i \in X} \frac{|\vec{p}_{i\perp}|}{\sqrt{s}} e^{-|\eta_i|(1-\alpha)}$$

where $p_{i\perp}$ is the transverse momentum with respect to the thrust axis of the event, and $\eta_i$ is the rapidity of the $i$'th particle. The thrust axis $\hat{t}$ is defined via $\max_{i} \sum_{i \in X} |p_i \cdot \hat{t}|/\sqrt{s}$. Two particularly interesting event shapes are the limits $a = 0, 1$ corresponding to "thrust" and "jet broadening" respectively. The limit $\varepsilon \ll 1$ isolates events composed of back to back jets. In the case of thrust these jets are composed of collinear radiation, and the recoil due to soft (ultra-soft in this case) radiation does not affect the jet axis. While for jet broadening all radiation with parametrically similar transverse momentum can contribute, so that soft radiation of the form $Q(\lambda, \lambda, \lambda)$ recoils the jet off the thrust axis. In both of these cases fixed order perturbation theory will fail when $\varepsilon$ is small. However, as long as $eQ \gg \Lambda_{QCD}$, we expect non-perturbative effects to be suppressed, though large logs of $\varepsilon$ need to be resummed.

The pioneering work on jet broadening resummations \cite{pioneering} utilized the coherent branching formalism \cite{coherent}. It was later stated \cite{later} that the results in \cite{pioneering} neglected terms due to recoil of soft gluons. In this letter we will provide a factorization theorem for jet broadening, whose proof will follow in a subsequent publication \cite{factorize}. The factorization proofs for angularity observables \cite{angular} in \cite{factorize} are known to fail as $a$ approaches 1, since there are growing power corrections in this limit where one approaches jet broadening. The reason for the apparent breakdown of factorization is the fact that in this limit the soft radiation has the same invariant mass as collinear radiation and one must change the power counting accordingly to factorize in a consistent fashion \cite{factorize}.

Hereforth, we set $a = 1$ and $e(1) \equiv e$. In \cite{factorize} prove that the cross section for jet broadening takes the following factorized form

$$\frac{d\sigma}{de} = \sigma_0 H(s) \int dp_{1t} dp_{2t} J_n(Q_+,e_+,p_{1t}) J_n(Q_-,e_-,p_{2t}) S(e_+,p_{1t},p_{2t})$$
$Q^\pm$ are the large light cone momenta of the jets with constraint $Q^+Q^- = s$, the center of mass energy.  

As long as $\sqrt{s}\epsilon \gg \Lambda_{QCD}$ all of these matrix elements are calculable in perturbation theory. The bare matrix elements possess both rapidity and UV divergences. Thus standard dimensional regularization is insufficient to regulate all the integrals. Beyond tree level one is immediately met with the aforementioned rapidity divergences. To regulate these integrals we introduce a regulator into the momentum space SCET Wilson lines as follows

$$W_n = \left[ \sum_{\text{perm}} \exp \left( -\frac{g}{n \cdot P} \left[ \frac{w_0}{\nu - \eta} \cdot A_{n,q}(0) \right] \right) \right],$$

$$S_n = \left[ \sum_{\text{perm}} \exp \left( -\frac{g}{n \cdot P} \left[ \frac{2\hat{P} - \eta/2}{\nu - \eta/2 - \eta} \cdot A_{s,q}(0) \right] \right) \right],$$

where $\nu$ is an arbitrary scale independent of the usual scale $\mu$ introduced in dimensional regularization. $w$ is a bookkeeping parameter which will be set to one at the end of the calculation. $\hat{P}^\mu$ is the momentum operator and we have essentially regulated the energy of the emitted gluons in each Wilson line, since $2F_0 \rightarrow n \cdot P$ in the collinear limit. Notice the factor of $\eta/2$ in the soft function. This choice is not a matter of convention. Physically, the factor arises as a consequence of the fact that soft must be cut-off at both positive as well as negative rapidity [14]. The Wilson line regularization breaks manifest boost symmetry, which is restored once all of the sectors are combined. The rapidity divergences for the jet and soft functions will introduce a new set of anomalous dimensions ($\gamma''_J, \gamma''_S$) which are defined via variation of $\nu$. Given that the hard function has no such anomalous dimensions, we must have the relation

$$2\gamma''_J + \gamma''_S = 0,$$  

or equivalently it must be true that the total $\eta$ dependence must vanish. Indeed it is not hard to show [13], that the sum of the $\eta$ divergences cancels as a consequence of eikonalization. This cancellation also implies that the individual factors $J$ and $S$ are multiplicatively renormalizable.

The tree level jet function is given by $\delta(e_n - p_{1t}/\sqrt{s})$ and soft function by $\delta(e_s)\delta(p_{1t})\delta(p_{2t})$. To determine the relevant scales in the logs, we must convolve the renormalized one-loop jet function with the tree level soft function as dictated in [4]. This is most easily seen for the integrated cross-section $\Sigma = \int_{t_0}^{s_0} de \left( d\sigma/dxe \right)$. At order $\alpha_s$, the result of the convolution leads to the following singular contributions from a jet

$$\frac{1}{\sigma_0} \Sigma_{\text{jet}} = -\frac{\alpha_s C_F}{2\pi} \ln(\sqrt{s_{e0}}/2\mu) \left[ 3 + 4 \ln(\sqrt{s}/Q^\pm) \right].$$

It thus becomes clear that the jet function depends on two different kinematical scales ($\sqrt{s_{e0}}$ and $Q^\pm$). In addition, we see that dependence on rapidity manifests in the form of the rapidity log, $\ln(Q^\pm/\nu)$. While the soft function singular contributions are

$$\frac{1}{\sigma_0} \Sigma_{\text{soft}} = \frac{\alpha_s C_F}{\pi} \left[ -2 \ln(\sqrt{s_{e0}}/2\mu) + 4 \ln(\ln(\sqrt{s_{e0}}/2\mu) \right],$$

and has rapidity logs set at the low scale $\sqrt{s_{e0}}$.

The utility of $\nu$ is clear as we may choose $\nu \sim Q^\pm \sim \sqrt{s}$ and $\mu \sim \sqrt{s}$ to minimize the logs in the jet function. Then to minimize the logs in the soft function we run $\nu$ from the scale $\sqrt{s_{e0}}$ up to $\sqrt{s}$. Furthermore we will need to run the hard matching coefficient down to the scale $\sqrt{s_{e0}}$ in the dimensional regularization parameter $\mu$. This scenario is shown schematically in Fig. 2.

Here we will perform the running at next to leading log (NLL) , which sums all terms of order one, where we take the scaling $\alpha_s \ln(e) \sim 1$. The NNLL analysis will be performed in [14]. The hard function RGE is well known to NNLL (see [12]). The running is most simply performed in Laplace transform space, with $(b,b')$ conjugate to $(p_{1t}, p_{2t})$ respectively. We find

$$\gamma^S(b, b') = -2\Gamma_c [(\log(bb' e^{\gamma_e}) + \log(b'e^{\gamma_e})],$$

where $\Gamma_c$ is the usual cusp anomalous dimension for Wilson lines. Similar equations can be written for the two jet functions in terms of their corresponding anomalous dimensions.

In our strategy of resumming logs for the soft function we only need two-loop cusp. Solution of the $\nu$-RGE for the soft function is

$$S(\mu, \nu) = V_s(\mu, \nu/\nu_0) \otimes S(\mu, \nu_0)$$

where $\otimes$ represents convolution in kinematical arguments which are dropped for brevity. Here,

$$V_s(p_{1t}, p_{2t}; \omega_s(\mu, \nu/\nu_0)) = e^{-2\gamma_\omega \omega_s}$$

$$\left( \frac{\omega_s}{\mu'} \left[ \frac{1}{(p_{1t}/\mu')^{1-\omega_s}} \right] + \delta(p_{1t}) \right) \left( \frac{\omega_s}{\mu'} \left[ \frac{1}{(p_{2t}/\mu')^{1-\omega_s}} \right] + \delta(p_{2t}) \right),$$

with $\omega_s(\mu, \nu/\nu_0) = 2\Gamma_c(\alpha_s(\mu)) \ln(\frac{s_{e0}}{\nu_0})$. To minimize logs in the hard function we need to evolve the hard function using

$$H(s; \mu) = H(s; \mu_0) U_H(s; \mu_0, \mu)$$

FIG. 2. Running Strategy.
where up to NLL $U_H$ can be found in [12], and $H(s, \mu_0) = 1$ to the order we are working.

The results we have presented so far are for the angularity at $a = 1$, which is related to the total jet broadening $B_T$ via $e = 2B_T$. We will present cross-sections for total jet broadening here and compare with the data. For NLO singular cross-section we get

$$\frac{d\sigma}{dB_T} = \sigma_0 \frac{\alpha_s(\mu) C_F}{\pi B_T} (3 - 4 \log B_T)$$

(14)

where $\sigma_0$ is the Born cross-section. This result is in agreement with ref. [8]. For the re-summed cross-section up to NLL order we have

$$\frac{d\sigma}{dB_T} = \frac{\sigma_0}{B_T} \frac{U_H(Q^2, \mu Q, \mu)}{\Gamma(2\omega_s) e^{2\pi\omega_s}} \left( \frac{Q B_T}{\mu} \right)^{2\omega_s}.$$  

(15)

In Fig. 3 we have plotted the theory cross section and the data [13]. We see that given the large error bars the agreement with the data is reasonable. However, the NNLL calculation will reduce the theory errors considerably. We have not included the theory errors due to power corrections. In the small $B_T$ region these are non-perturbative and scale as $\Lambda_{QCD}/(B_T Q)$ and can be expected to be of order 20-30%. In the tail region there are corrections of order $B_T$ to the singular contributions. The disagreement at intermediate values of $B_T$, where fixed order calculations suffice, is expected, since logs will not dominate in this region and NLL results leave off order one contributions. This region will be correctly reproduced in the NNLL calculation. Therefore, by systematically improving this result by including higher order corrections in $\alpha_s$, power corrections and non-perturbative correction, this result can be used for precision $\alpha_s$ determination. Such an analysis using thrust was done in [12].

Finally, we wish to point out that the rapidity renormalization group can be utilized in multiple other settings where rapidity divergences arise. Generically, this will occur whenever kinematically soft radiation has invariant mass of the same order as the collinear radiation, as in cases where one measures the $p_T$ of the final state. Such observables will be discussed in more detail in [14]. Furthermore, it would be interesting to utilize our rapidity renormalization group in the context of exclusive processes where it has been shown rapidity factorization sheds light on end point singularities in integrals over light-cone distribution functions [4].

We would like to thank Tom Ferguson for useful discussions regarding the data. We also thank I.W. Stewart for discussions. This work is supported by DOE Grants DOE-ER-40682-143 and DEAC02- 6CH03000. D.N. is supported by LHC-TI Graduate Fellowship NSF grant number PHY-0705682.
