(Received ; accepted )

Abstract

The Narrow-line Seyfert 1 galaxy 1H0707–495 is known to exhibit significant X-ray spectral variations. Its X-ray energy spectrum is characterized by a strong soft excess emission, an extremely deep iron K-edge structure at ∼7 keV, and a putative iron L-line/edge feature at ∼1 keV. We have found that the energy spectrum of 1H0707–495 in 0.5–10 keV is successfully explained by a “variable double partial covering model” where the original continuum spectrum, which is composed of the soft multi-color disk blackbody component and the hard power-law component, is partially covered by two ionized absorption layers with different ionization states and the same partial covering fraction. The lower-ionized and thicker absorption layer primarily explains the iron K-edge feature, and the higher-ionized and thinner absorption layer explains the L-edge feature. We have discovered that the observed significant intensity/spectral variation within a ∼ day is mostly explained by only variation of the partial covering fraction. In our model, the intrinsic luminosity and spectral shape are hardly variable within a ∼ day, while some intrinsic variability above 3 keV is recognized. This is consistent with the picture that the multi-color disk blackbody spectrum is almost invariable in this timescale, and the hard power-law component is more variable. We propose that the observed spectral variation of 1H0707–495 is caused by three physically independent variations with different timescales; (1) intrinsic luminosity variation over days, (2) variation of partial covering fraction at a timescale of hours, and (3) small intrinsic hard component variation above 3 keV in a timescale of hours or less.

Key words: galaxies: active — galaxies: individual (1H0707–495) — galaxies:
1. Introduction

Narrow-line Seyfert 1 galaxies (hereafter, NLS1s) are known to have narrower Balmer lines than usual Seyfert 1 galaxies (Osterbrock & Pogge 1985), strong FeII emission (Halpern & Oke 1987), steep X-ray photon indices (Puchnarewicz et al. 1992), and intense X-ray flux/spectral variation (Ulrich et al. 1997). The narrow line widths imply shallow gravitational potential around the central black holes, which is due to small black hole masses. Strong FeII emission, steep X-ray photon indices, and intense X-ray time variation imply high accretion rates, which mean the high Eddington ratios (Sulentic et al. 2000; Boroson 2002). The small black hole masses and high gas accretion rates suggest that the black holes are rapidly evolving young systems, where the elapsed time from the onset of the gas inflow is rather short (Mathur 2000). Therefore, NLS1s are considered to be in an early phase of the AGN evolution (Grupe 2004).

Among NLS1s, 1H0707–495 is characterized by a sharp spectral drop at $\sim 7$ keV, a strong soft excess emission, and a hint of iron L-edge feature (Boller et al. 2002). Several different models have been proposed to explain its unique X-ray energy spectrum. On one hand, some explain these features in terms of the “relativistic disk-line model,” where relativistically blurred inner-disk reflection around an extreme Kerr black hole is supposed to take place and be responsible for these spectral features (e.g., Fabian et al. 2009). In this model, the spectral variation is interpreted to be mostly caused by changes in the geometry in the very vicinity of the black hole, such as the height of the continuum source above the black hole (Fabian et al. 2002; Fabian et al. 2004). On the other hand, a partial covering model may also explain these spectral features. Gallo et al. (2004) attempted to explain the long-term spectral changes with the partial covering by a neutral single-layer absorber with iron-overabundance ($\sim 3\times$ solar). Tanaka et al. (2004) used a double-layer neutral partial covering model, and suggested that the partial covering clouds are produced presumably due to either disk instabilities or radiation-driven mass outflow. In these models, the observed X-ray spectral variation is, at least to some extent, explained by change of the partial covering fraction.

Meanwhile, Miyakawa et al. (2012) has shown that a characteristic broad iron-line feature and spectral variation of the Seyfert 1 galaxy MCG-6-30-15, which is often classed as an NLS1 (McHardy et al. 2005), are successfully explained by a variable partial covering model. In this model, intrinsic X-ray luminosity and spectral shape of the central X-ray source are not significantly variable; the observed flux and spectral variations are explained mostly by variation of the partial covering fraction by intervening absorbers, which are composed of two different ionization layers. Here, we apply the variable partial covering model for the XMM-Newton...
and Suzaku observations of 1H0707–495, to see if this model is also valid in explaining spectral variations of another NLS1 that is known to exhibit extreme spectral characteristics. We examine in this paper whether spectral variation is explained even if we assume no intrinsic variation.

We first describe the data we use in Section 2. Next, in Section 3, we show that the spectral model used for MCG-6-30-15 by Miyakawa et al. (2012) is considered to be a “Variable Double Partial Covering (VDPC) model”, and that the VDPC model can explain the X-ray spectral variation of 1H0707–495. Section 4 gives further details on interpretation of the X-ray spectral variation. Finally, we show our conclusions in Section 5.

2. Observation and Data Reduction

The XMM-Newton satellite (Jansen et al. 2001) observed 1H0707–495 fifteen times, and the Suzaku satellite (Mitsuda et al. 2007) did once. These observation IDs, start dates, and exposure times are listed in Table 1.

In the XMM-Newton data analysis, we used the European Photon Imaging Camera (EPIC)-pn data (Strüder et al. 2001) in 0.5–10.0 keV and the reflection grating spectrometer (RGS: den Herder et al. 2001) in 0.5–1.5 keV. For XMM-Newton data reduction, we used the XMM-Newton Software Analysis System (SAS, v.12.0.1) and the latest calibration files as of March 2013. The EPIC-pn spectra and light-curves were extracted with \texttt{PATTERN} \leq 12 \footnote{We also tried the selection \texttt{PATTERN} \leq 4 instead of \texttt{PATTERN} \leq 12, but the results were almost the same within statistical error.} from the circular regions with 20\arcsec radius centered on the source, while background products were extracted from the annulus region of the inner and outer radius of 45\arcsec and 75\arcsec, respectively. High background period is excluded, when the count-rate of 10–12 keV with \texttt{PATTERN} \equiv 0 is higher than 0.4 cts/s. The RGS spectra were processed with task \texttt{rgsproc}.

In the Suzaku data analysis, we used the X-ray Imaging Spectrometer (XIS) data in 0.7–10.0 keV, while we did not use the hard X-ray detector (HXD) PIN diode data because significant signals were hardly detected above 10 keV. Since contamination calibration on the XIS window is not fully achieved, we did not use the XIS data below 0.7 keV. For Suzaku data reduction we used the HEADAS 6.15.1 software package. The XIS data were screened with \texttt{XSELECT} using the standard criterion (Koyama et al. 2007). The XIS spectra and light-curves were extracted from circular regions of 3\arcmin radius centered on the source, while background products were extracted from the annulus region of the inner and outer radius of 4\arcmin and 7\arcmin respectively. We generated XIS response matrices using the \texttt{xisrmfgen} software, which takes into account the time-variation of the energy response. As for generating ancillary response files (ARFs), we used \texttt{xissimarfgen} (Ishisaki et al. 2007). This tool calculates ARFs through ray-tracing, and we selected the number of input photons as 400,000, with the “estepfile” parameter.
“full”. After extracting the products for the back-illuminated (BI) CCD (XIS 1) and for the three front-illuminated (FI) CCD XIS detectors (XIS 0, XIS 2, XIS 3) separately, we confirmed that the XIS 0, XIS 2, and XIS 3 products are almost identical to each other. We thus combined the XIS 0, XIS 2, and XIS 3 products in our spectral analysis, using addascaspec to create the merged XIS spectra and responses.

All the spectral fitting were made with xspec v.12 (Arnaud 1996). In the following, the xspec model names used in the spectral analysis are explicitly given.

3. Data Analysis and Results

3.1. Variable Double Partial Covering Model

First, we try to fit the time-average spectrum of each observation using a similar spectral model that was successful for MCG-6-30-15. Miyakawa et al. (2012) adopted the following spectral model to fit the MCG-6-30-15 (see their Equation (2)),

\[
F = W_H W_L (N_1 + N_2 W_2) P + N_3 R P + I_{Fe},
\]

where \( P \) is the intrinsic power-law spectrum, \( R \) is the outer disk reflection albedo, and \( I_{Fe} \) is the fluorescent narrow iron emission line. \( N_1 \) is the normalization of the direct (non-absorbed) component, and \( N_2 \) is the normalization of the heavily absorbed component, where \( W_2 \) indicates the ionized thick partial absorber \( (N_H \approx 1.6 \times 10^{24}\text{cm}^{-2} \text{ and } \log \xi \approx 1.57) \), and \( N_3 \) is the normalization of the disk reflection component. \( W_H \) and \( W_L \) are high-ionized and low-ionized warm absorbers, both of which are optically thin.

MCG-6-30-15 shows ionized iron K-absorption lines, which are explained by \( W_H \), where \( N_H \approx 2.4 \times 10^{23} \text{ cm}^{-2} \text{ and } \log \xi \approx 3.4 \) (Table 1 in Miyakawa et al. 2012). However, in the case of 1H0707–495, these iron K-absorption lines are not observed, which indicates that \( W_H \) is not necessary. Also, a fluorescent narrow iron emission line, which is accompanied by outer disk reflection, is not recognized in 1H0707–495 either. Hence, we consider the following simple form of the model,

\[
F = W_L (N_1 + N_2 W_2) P
= W_L N (1 - \alpha + \alpha W_2) P,
\]

where we have introduced the total normalization factor \( N \equiv N_1 + N_2 \) and the partial covering fraction \( \alpha \equiv N_2/N \). Here, \( W_L \) can be written as

\[
W_L = \exp (-\sigma(E,\xi)N_{H,L}),
\]

where \( \sigma(E,\xi) \) is the cross-section and \( N_{H,L} \) is the column density of the low-ionized absorber. Miyakawa et al. (2012) discovered that, in the course of spectral variation of MCG-6-30-15, \( N_{H,L} \) and \( \alpha \), which are in principle independently variable, are clearly correlated to each other. Namely,
\[ N_{H,L} = \alpha N_{H,L}^{(\text{fixed})}, \]  
\[ \text{(4)} \]

where \( N_{H,L}^{(\text{fixed})} \) is invariable (Equation (8) in Miyakawa et al. 2012). This finding, which shows that the two independent absorbers are correlated, was unexpected and rather surprising. Considering that \( W_L \) is optically thin, from Equation (3) and (4),

\[ W_L \approx 1 - \sigma(E,\xi)N_{H,L} \]
\[ = 1 - \alpha \sigma(E,\xi)N_{H,L}^{(\text{fixed})} \]
\[ \approx 1 - \alpha + \alpha \exp\left(-\sigma(E,\xi)N_{H,L}^{(\text{fixed})}\right) \]
\[ = 1 - \alpha + \alpha W_L^{(\text{fixed})}, \]  
\[ \text{(5)} \]

where we introduced \( W_L^{(\text{fixed})} \equiv \exp\left(-\sigma(E,\xi)N_{H,L}^{(\text{fixed})}\right) \). In the end, Equation (2) may be written as,

\[ F = N(1 - \alpha + \alpha W_L^{(\text{fixed})})(1 - \alpha + \alpha W_2)P. \]  
\[ \text{(6)} \]

Namely, the spectral model Miyakawa et al. (2012) proposed is mathematically identical to a “double partial covering model,” which is similar to the one used by Tanaka et al. (2004). Difference of our model from that by Tanaka et al. (2004) is that we assume that the two absorption layers have the same covering fraction and different ionization states, while Tanaka et al. (2004) assumed that the two partial absorbers have different covering fractions and that both are neutral. We again stress that, in this model, the two warm absorbers with different ionization degrees have the same covering fraction. Presumably, the partial covering clouds have internal layers that contain the thick/low-ionized core and thin/high-ionized envelope (Miyakawa et al. 2012), so that the two absorption layers have the same covering fraction.

Additionally, considering the soft excess component, interstellar absorption and strong Fe L- and K-shell edges, the model we use to fit 1H0707–495 spectra is

\[ F = A_I N(1 - \alpha + \alpha W_n e^{-\tau_1})(1 - \alpha + \alpha W_k e^{-\tau_2})(P + B) \]  
\[ \text{(7)} \]

where \( B \) is the spectrum from an accretion disk (we adopted diskbb in xspec), \( A_I \) is the effect of interstellar absorption (wabs), and \( W_n \) and \( W_k \) are hotter/thinner and colder/thicker partial absorbers, respectively. The Fe L- and K-shell edges are mostly explained by \( W_n \) and \( W_k \), respectively, but additional edge components were introduced as \( e^{-\tau_1} \) and \( e^{-\tau_2} \) when needed. It should be noted that the additional edges are put only to the spectral components that pass through the absorbers.

To model the warm absorbers, we used the absorption table calculated with XSTAR (Kallman et al. 2004) by Miyakawa et al. (2009), assuming the solar abundance and the photon index of the ionizing spectrum 2.0. Hereafter, Equation (7) is our baseline model, which we call the VDPC model, where the partial covering fraction \( \alpha \) is mostly variable and other spectral parameters are not significantly variable within an observation, as indicated for MCG-6-30-15 by Miyakawa et al. (2009). We note that parameters besides the partial covering fraction \( \alpha \) are
variable for different observations (= at timescales over several days.)

3.2. Spectral Fitting to the Average Spectra

First, we consider the time-average spectra for the individual observations in Table 1. The spectra are studied under the assumption of the VDPC model given in Equation (7). Figure 1 shows the fitting result for the total time-average spectra. The fitting parameters and the reduced chi-squares are shown in Table 2. Errors are quoted at the statistical 90% level. The foreground absorption was estimated as $N_H = 4 \times 10^{20} \, \text{cm}^{-2}$ from the Leiden-Argentice-Bonn 21 cm survey (Kalberla et al. 2005). However, when we fix the interstellar absorption, there remain some residuals in the soft band, suggesting existence of some excess absorption. Thus, we allow the interstellar absorption to be variable, following Dauser et al. (2012). This may be due to additional intrinsic absorption associated with 1H0707–495.

Most spectra are fitted reasonably well, where complex iron L- and K-features at $\sim 1$ keV and $\sim 7$ keV are primarily explained by partial covering by the hotter/thinner absorber ($W_n$) and colder/thicker absorber ($W_k$), respectively. However, we note that there remain some residuals around 1 keV of the spectra with long exposure time (especially in XMM7, 11, 12, 13, and 14.) These residuals may be explained by the fact that the time-averaged spectra of the VDPC model, where partial covering fraction is the only variable parameter, is not mathematically identical to the VDPC model with the average partial covering fraction. This situation is explained in the Appendix. We note that the XMM15 observation was triggered after the source flux was significantly dropped compared with that of the 2008 observations (Fabian et al. 2012). Thus, parameters of the intrinsic X-ray spectrum were drastically changed compared with those of the 2008 observations.

3.3. The RGS spectra

In the VDPC model, the absorption edge/line features from the warm absorbers are expected in the X-ray spectra. In fact, presence of some absorption-like features have been pointed out by Dauser et al. (2012). On the contrary, Blustin & Fabian (2009) claimed that XMM-Newton RGS observations have few narrow absorption lines and show little evidence for a line-of-sight ionized winds or warm absorbers. To examine this claim, we analyze the RGS data to see if they are consistent with presence of the ionized warm absorbers expected from the VDPC model. Figure 2 shows the XMM7–10 combined RGS spectra, which is the same as what Blustin & Fabian (2009) analyzed with the best-fit VDPC model for the EPIC-pn time-average spectrum. In the model spectrum, many absorption lines are clearly recognized. However, even the strongest hydrogen-like oxygen Lyman $\alpha$ line is not clearly recognized in the RGS spectrum, because of the limited statistics. This result shows that the high-resolution RGS spectra are consistent with the VDPC model with weak but plenty of absorption lines.
3.4. Spectral Fitting to the Sliced Spectra

Next, we apply the VDPC model to “intensity-sliced spectra” to investigate spectral variation at time-scales shorter than a ∼ day. The method for creating the intensity-sliced energy spectra is as follows: (1) We create light-curves with a bin-width of 128 sec in the 0.2–12.0 keV band (see Figure 3). (2) We calculate all counts in each data and determine the four intensity ranges (separated by horizontal lines in Figure 3) that contain almost the same counts. (3) From the four time-periods corresponding to the different source flux levels, we create the four intensity-sliced energy spectra.

First, we examine if spectral shape is truly variable for intensity-sliced spectra within an observation. To that end, we first try to fit the intensity-sliced spectra only changing the normalization. Figure 4 shows the result of XMM12, which exhibits a wide spectral variation. Here, only normalizations of the intrinsic power-law and MCD are variable (ratio of the two components is fixed), while all of the other spectral parameters are common. The reduced chi-square is 3.24, which clearly indicates that the observed spectra are significantly variable.

So, next we examine if the observed spectral variation within an observations is explained only varying the partial covering fraction. During each observation, whose duration is from 40 ksec (XMM3 and 4) to 250 ksec (Suzaku), we assume that the intrinsic source luminosity and the spectral shape are invariable, and that the spectral variation is caused by only change of the partial covering fraction. For each observation, all the spectral parameters are common to the four spectra, except for the covering fraction. The fitting results are shown in Figure 5 and Table 3. In spite of the fact that our spectral variation model is extremely simple with only a single variable parameter, we see that the 0.5–10 keV XMM and Suzaku spectral variations are explained reasonably well, where the reduced chi-square values (degree of freedom) are from 1.07 (1358) to 1.65 (451). We also find that normalizations and other parameters of the disk blackbody component and the power-law component are significantly variable between observations, indicating that the intrinsic luminosity and spectra are variable in timescales longer than ∼ days.

3.5. Time-Variation of the different energy bands

We find, in the above subsection, that the VDPC model can explain the intensity-sliced spectra by only change of the covering fraction, where the luminosity is constant over the observation period for a ∼ day. Next, we examine if shorter timescale variations are also explained with the VDPC model. To that end, we create simulated light-curves via the VDPC model for several different energy bands varying only the partial covering fraction, and compared them with the observed light-curves in these energy bands.

The method to create the simulated light-curves is as follows: (1) For each observation, we fix all the model parameters besides the partial covering fraction at the best-fit values obtained from the intensity-sliced spectral analysis (Table 3). (2) For each light-curve bin,
which is 512 sec, the partial covering fraction value is calculated so that the observed counting rate in 0.5–10.0 keV and the model counting rate match. (3) Given the partial covering fraction value thus determined for each bin, we create the simulated spectra using `fakeit` command in `xspec`, and calculate the simulated count-rates in 0.5–1.0 keV (soft), 1.0–3.0 keV (medium), and 3.0–10.0 keV (hard) respectively (Figure 6). (4) We compare the simulated light-curves in the three bands with the observed ones.

In Figure 7, we show comparison of the observed light-curves and model light-curves, as well as variation of the partial covering fraction. We find that the observed light-curves in the soft band is almost fully reproducible by the VDPC model with only variation of the partial covering fraction, while the agreement becomes less satisfactory toward higher energy bands. This may suggest that the VDPC model with a single variable parameter is too simple to fully explain the hard-band spectral variation; in fact, some hard flare-like events have been reported independently of the soft-band variation (e.g., Leighly 2004). In any case, we stress that the VDPC model can reproduce the observed light-curves at the accuracy manifested in Figure 7 that demonstrates that the partial covering phenomenon does take place in 1H0707–495 and plays a major role to cause apparently significant intensity/spectral variations.

4. Discussion

4.1. Spectral features

In addition to the cold/thick and hot/thin absorbers that respectively explain the iron K- and L- edges, we had to introduce the ad-hoc edge components to explain the extremely strong edge features. We conjecture that the extremely strong iron edges might be due to either Fe overabundance and/or P Cygni profiles produced by winds. When the iron is over-abundant as much as several times, the strong spectral drops may be explained (Tanaka et al. 2004). Besides, if the velocity of the partial absorbers is $\sim 0.3c$, the iron line profiles would become P Cygni profiles and may explain the drops, as discussed by Done et al. (2007) (see also Turner 2014). The “P Cygni” hypothesis is consistent with our model in Section 4.3, which suggests that the partial covering clouds are in the clumpy line-driven disk winds. In this scenario, variation of the apparent edge energy (see Tables 2 and 3) may be explained by change of an ionization degree or wind structures (Done et al. 2007).

4.2. Timescale of variations

In Section 3, we have shown that the VDPC model is successful to explain the observed light-curves in a timescale shorter than $\sim$ days, with only change of the partial covering fraction. In particular, the simulated light-curves and observed ones below 3 keV are surprisingly identical. This suggests that the intrinsic X-ray luminosity and spectral shape are almost invariant.

---

2 The proceeding (Turner 2014) is available at [http://xmm.esac.esa.int/external/xmm_science/workshops/2014symposium/presentations/TTurner_t.pdf](http://xmm.esac.esa.int/external/xmm_science/workshops/2014symposium/presentations/TTurner_t.pdf)
within a ∼ day, and variation of the partial covering fraction is the main cause of the observed spectral variation. We see that the range of covering fraction variation is large, from null to ∼ 90 % (Figure 7), which suggests that absorbing clouds in the line-of-sight are comparable in size to the central X-ray emitting region, and fluctuating to cover/uncover the central source, independently of status of the central source.

While the covering fraction variation can almost reproduce the light-curves, there remain some residuals above 3 keV. When we assume there is no intrinsic variation in our model, the residuals between the observation and the model indicates real intrinsic variation. Figure 8 shows ratios of the observed light-curves to the simulated ones, the energy band and time-bin of which are the same as those of Figure 7. This figure shows intrinsic variations that cannot be explained by only variation of the covering fraction do remain in the hard energy band. To evaluate the residuals, we calculate the root-mean-square of the residuals between the observation and the model (Figure 9). We defined the RMS of the residuals as $\sqrt{\sum_i^N ((\text{observed}_i - \text{model}_i)/\text{model}_i)^2/N}$ in the three energy bands. Figure 9 clearly shows that the residuals are more significant in the hard energy band, where the power-law component is dominant. This suggests that the power-law variation causes the intrinsic variation in the hard energy band, which is consistent with the light-crossing time of X-ray emitting region, ∼ 500 sec, when assuming that black hole mass is $10^{6.37} M_\odot$ and the Schwarzschild radius is $r_s \approx 6 \times 10^{11}$ cm. (See Section 4.3 for the validity of these values.) On the contrary, little intrinsic variation is seen in the soft energy band, where the multi-color disk component is dominant. This suggests that the viscous time of the disk is longer than the timescale of an observation.

While the intrinsic luminosity seems almost invariant within a day, comparing XMM1 with XMM2, for example, variation of the intrinsic luminosity is about an order of magnitude over 2 years. Even during a shorter interval, between XMM12 and XMM13, as an example, variation of the intrinsic luminosity is about a factor of two over 2 days. The standard disk may not explain such a large fluctuation in the soft X-ray emission as well as the high disk temperature (Tables 2 and 3) observed in 1H0707–495 (Mineshige et al. 2000; Tanaka et al. 2004). Assuming that 1H0707–495 has a slim-disk (Mineshige et al. 2000), a large variation of the mass-accretion rate might explain these significant luminosity variations over days (Gallo et al. 2004).

NLS1s have been known to exhibit significant intensity and spectral variations at various timescales (see e.g. Leighly 1999.) Our result indicates that this is due to combination of the variations in the intrinsic luminosity and in the covering fraction of the intervening absorbers at different timescales. In summary, we propose that spectral variation of 1H0707–495 mainly consists of the two independent types of variations with different timescales; (1) intrinsic luminosity variation over days, and (2) variation of partial covering fraction at a timescale of hours.
4.3. Property of partial absorbers

Zoghbi et al. (2010) pointed out that the X-ray energy spectrum of 1H0707–495 is composed of at least two components, one dominating between 1 and 5 keV, the other dominating above the 1–5 keV range. The VDPC model, in which the multi-color disk component and the high-ionized absorber determine the soft spectrum below ∼ 3 keV, while the power-law component and the low-ionized absorber determines the hard spectrum over ∼ 3 keV, is consistent with this spectral picture. Tanaka et al. (2004) assumed that the covering fraction varies with the orbital motion of the clouds, and suggested that the clouds are rotating at around $r \sim 400 r_s \left( \sim 2 \times 10^{14} \right)$ cm. However, if the partial covering clouds are uniformly surrounding the central source, that would produce Fe-K fluorescence lines; this contradicts with absence of such lines (Zoghbi et al. 2010). Namely, most of the partial covering clouds should exist in the line-of-sight not to produce the significant fluorescent iron emission line. Therefore we suspect that the partial covering clouds are in the clumpy line-driven disk wind, which is thought to be an origin of the outflows (Stevens & Kallman 1990). Since the realistic radiation-hydrodynamic simulations show funnel-shaped disk winds (Proga et al. 2000; Proga & Kallman 2004), when the line-of-sight is close to the tangential line of the disk wind, we may observe the X-ray energy spectrum with hardly fluorescent iron emission line but significant absorption features.

Next, we estimate location of the warm absorber $W_n$, which is considered to be photoionized by the central X-ray source, in a similar manner suggested by Miyakawa et al. (2012). We use the following relations:

$$\xi \equiv \frac{L}{n r^2} = \frac{L_d}{N_H r^2}, \text{ where } N_H = n d,$$

(8)

$$r = \left( \frac{L_d}{\xi N_H} \right)^{1/2},$$

(9)

where $r$ is distance from the central X-ray source to the absorber, $d$ is a representative thickness of the absorbing region along the line-of-sight, $n$ is density and $L$ is the intrinsic luminosity.

We found the partial covering fraction varies from null to ∼ 0.9, that suggests that the partial absorber size is comparable to that of the central source, otherwise we would see a full covering (when the absorber size is much larger than the source size), or the variation amplitude should be much smaller (when opposite.) When the source is not significantly variable, the covering fraction is not so variable for about $10^4$ sec (see, e.g., the top panel of Figure 7) which we take as a typical crossing timescale of the partial absorbers in front of the central X-ray source. The crossing timescale may be expressed as $\sim d/v$, where $v$ is the velocity of partial absorbers. Hence,

$$d \sim v \times 10^4 \sim 10^{13} \left( \frac{v}{10^9 \text{ cm s}^{-1}} \right) \text{ cm},$$

(10)

where $v$ is normalized to that of a typical line-driven disk wind (Proga et al. 2000). Here we take typical values of $N_H = 5 \times 10^{21}$ cm$^{-2}$, $\log \xi = 3$ for $W_n$, $L = 10^{43}$ erg s$^{-1}$ expected by the
parameters of power-law and multi-color disk in Table 3. We thus estimate the distance from the central X-ray source to the absorber as follows:

$$r = \left( \frac{L}{\xi N H d} \right)^{1/2} \approx 10^{14.5} \text{ cm.}$$

(11)

Black hole mass of 1H0707–495 is estimated to be $10^{6.37} M_\odot$ from the empirical reverberation relation (Zhou & Wang (2005) and references therein), and the Schwarzschild radius is $r_s \approx 6 \times 10^{11} \text{ cm}$. Therefore, our analysis suggests that typical sizes of the X-ray emission region and the partial absorbers are $\sim 20 r_s$, and the absorbers are typically located at $\sim 500 r_s$ from the black hole. This is consistent with numerical simulations of the disk wind accelerated by a radiation force due to spectral lines (line force), which shows that the wind is launched within several $100 r_s$ radius (e.g., Nomura et al. 2013). In addition, this is also consistent with an X-ray time-lag analysis in a wide energy band of 1H0707–495, which suggests that an absorbing medium that partially-covers the source at $20–100 r_s$ from the black hole may be the cause of the observed energy dependent reverberation time-lags (Miller et al. 2010).

5. Conclusion

We have analyzed all the currently available XMM-Newton and Suzaku archival data of NLS1 1H0707–495, the total exposure time of which is $\sim 1070 \text{ ksec}$. We have found that the observed spectral variation is successfully explained by the VDPC model. Our main conclusions are as follows:

1. We have shown that the spectral model Miyakawa et al. (2012) proposed to explain the spectral variation of MCG-6-30-15 is identical to a “variable double partial covering model”, which we denote the VDPC model in this paper, where two partial absorption layers have different ionization states and the same covering fraction.
2. The intensity-sliced spectra of 1H0707–495 within a $\sim$ day are successfully fitted with the VDPC model only varying the partial covering fraction. Light-curves within a $\sim$ day are also explained with the VDPC model only varying the partial covering fraction, where the agreement between the observation and the model is remarkable in the soft energy band (0.5–1 keV), while less satisfactory in higher energy bands. Some intrinsic variation is recognized above $\sim 3 \text{ keV}$.
3. Over timescales of $\sim$ days, intrinsic luminosity/spectral variations are significant, such as a factor of two over 2 days, or an order of magnitudes over 2 years.
4. We propose that the spectral variation of 1H0707–495 consists of the three types of variations with different timescales: (1) intrinsic luminosity variation over days, (2) variation of partial covering fraction at a timescale of hours, and (3) small intrinsic hard component variation above 3 keV in a timescale of hours or less.
5. We suggest that the absorbing clouds are clumpy radiatively-driven disk winds localized...
in the line of sight. We estimate the X-ray source size and typical cloud size $\sim 20 \, r_s$, and the clouds typically locate at $\sim 500 \, r_s$.

Finally, we point out that significant flux/spectral variations similar to that of 1H0707–495 are also observed from other NLS1s such as IRAS 13224–3809 (Boller et al. 2003), Mrk 335 (Longinotti et al. 2013), and Ark 564 (Brinkmann et al. 2007). It will be intriguing to apply the same analysis presented in this paper to these sources to see if the VDPC model is also valid and their significant spectral variations are explained by change of the partial covering fractions. If this is the case, that will be an important step toward a systematic understanding of the NLS1s.

This research has made use of public Suzaku data obtained through the Data ARchives and Transmission System (DARTS), provided by the Institute of Space and Astronautical Science (ISAS) at Japan Aerospace Exploration Agency (JAXA). This work is also based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and the USA (NASA), and the XMM-Newton data obtained through the High Energy Astrophysics Science Archive Research Center (HEASARC) at NASA/Goddard Space Flight Center.

For data reduction, we used software provided by HEASARC at NASA/Goddard Space Flight Center.
Table 1. Suzaku and XMM-Newton observations of 1H0707–495. Observation IDs, start date, and good exposure times in sec are indicated. The exposure time of Suzaku is that of XIS 0.

Table 2. Results of the average spectral fitting. Normalization of the power-law means the X-ray flux after removing the absorption in units of $10^{-12}$ erg cm$^{-2}$ s$^{-1}$ between 0.4–10 keV. The normalization of MCD means diskbb normalization, $(R_{in})/(km)/(D/10kpc))^2 \cos \theta$. Errors are quoted at the statistical 90% level. Often upper-limits of the edge depths are not determined, and only the lower-limits are shown.

Appendix. Non-identity of the time-average of the variable partial covering model spectra and the model spectrum with the average partial covering fraction

In the VDPC model we adopt in the present paper, the spectral shape is expressed with the “double partial covering” as Equation (7), and the spectral variation is explained by only variation of the partial covering fraction \( \alpha \). In this appendix, we explain that the time-average of the VDPC model spectra where the partial covering fraction is variable and the VPDC model spectrum with the average partial covering fraction are not mathematically identical.

In Equation (7), since the covering factor \( \alpha \) is the only time-variable, the spectrum \( F_i \) at a given time \( t_i \) is written as

\[
F_i = A_I N (1 - \alpha_i + \alpha_i W_n e^{-\tau_1})(1 - \alpha_i + \alpha_i W_k e^{-\tau_2})(P + B)
\]

\[
= A_I N \left( (1 - \alpha_i)^2 + (1 - \alpha_i) \alpha_i (W_n e^{-\tau_1} + W_k e^{-\tau_2}) + \alpha_i^2 W_n e^{-\tau_1} W_k e^{-\tau_2} \right) (P + B) \quad (A1)
\]

Thus the time-average spectrum \( F \) is expressed as

\[
F = \left( \frac{\sum_i^n F_i}{n} \right)
\]

\[
= A_I N \left( (1 - \alpha)^2 + (1 - \alpha) \alpha (W_n e^{-\tau_1} + W_k e^{-\tau_2}) + \alpha^2 W_n e^{-\tau_1} W_k e^{-\tau_2} \right) (P + B) \quad (A2)
\]

where \( K \equiv (\sum_i^n K_i)/n \). On the other hand, assuming that the time-average spectrum \( F \) is expressed by the same double partial covering model with the covering factor \( \beta \),

\[
F = A_I N \left( (1 - \beta)^2 + (1 - \beta) \beta (W_n e^{-\tau_1} + W_k e^{-\tau_2}) + \beta^2 W_n e^{-\tau_1} W_k e^{-\tau_2} \right) (P + B) \quad (A3)
\]

should hold.

So that Equation (A2) and (A3) agree, we should have

\[
\begin{align*}
(1 - \alpha)^2 &= (1 - \beta)^2 \\
(1 - \alpha) \alpha &= (1 - \beta) \beta \\
\alpha^2 &= \beta^2.
\end{align*}
\]

(A4)

By putting \( V(\{\alpha_i\}) \) as the variance of \( \{\alpha_i\} \), we have

\[
\alpha^2 = \bar{\alpha}^2 + V(\{\alpha_i\})
\]

(A5)

and

\[
\begin{align*}
1 - 2\bar{\alpha} + \bar{\alpha}^2 + V(\{\alpha_i\}) &= 1 - 2\beta + \beta^2 \\
\bar{\alpha} - \bar{\alpha}^2 - V(\{\alpha_i\}) &= \beta - \beta^2 \\
\bar{\alpha}^2 + V(\{\alpha_i\}) &= \beta^2.
\end{align*}
\]

(A6)

These three equations are only fulfilled when

\[
\bar{\alpha} = \beta
\]

(A7)

\[
V(\{\alpha_i\}) = 0.
\]

(A8)

Equation (A8) indicates that the time-averaged spectrum is identical with the VDPC model only when \( \alpha_i = \text{const.} \) i.e. there is no time variation. This also means that some residual
structures should appear when we attempt to fit the time-average of the VDPC model spectra with a VDPC model spectrum with the average partial covering fraction. This is due to non-linearity of the double partial covering model with \( \alpha \) (Equation A1). On the other hand, for example, a single-layer partial covering model given as

\[
F = A_I((1 - \alpha) + \alpha W)(P + B)
\]

(A9)

does not make such residuals because the model is linear with \( \alpha \); average of the time-variable single partial covering model spectra is mathematically identical to the same model with the covering factor \( \beta = \alpha \). We also note that the residuals are not made when the two covering fractions in a double-layer partial covering model are independent, or the covariance is zero.

To demonstrate this effect, we carried out spectral simulations assuming the best-fit VDPC model of the data set XMM1 (Table 3). We create the light-curve with a bin-width of 128 sec, where the best-fit covering fraction is determined for each light-curve bin. We create a simulated spectrum every 128 sec, and we integrated the simulated spectra. We fit the thus created time-averaged simulated spectrum with the VDPC model. For emphasizing the structure of simulated spectrum, we take simulated exposure time of each light-curve bin 100 Msec. The covering factors have \( \bar{\alpha} = 0.644 \), \( \bar{\alpha^2} = 0.440 \), and \( V(\{\alpha_i\}) = 0.025 \). Figure 10 shows the simulated time-averaged spectrum and the best-fit VDPC model with the covering factor \( \beta = 0.642 \). A significant residual structure is seen below 2 keV.

Some residuals around 1 keV have been reported in the energy spectrum of 1H0707–495, which were suggested as a blend of resonance absorption line of ionized iron L-shell and emission line arising from an extended warm medium (Gallo et al. 2004). Similar features have been also reported from IRAS 13224–3809 (Boller et al. 2003) and other NLS1s (Nicastro et al. 1999). Here, we suggest that these apparent residuals may be due to non-linearity of the model, such that a time-averaged spectrum of the VDPC model is not identical to the double partial covering model with the time-averaged partial covering fraction.
