ABSTRACT
This study found a new type of immobilized mycelial pellet GX-1310, which can better treat industrial wastewater. Among them, Aspergillus fumigatus G-13 (degradable lignin) was combined with Bacillus cereus X10-1-2 (having the ability to produce cellulase), and the two synergistically produce strong degradation ability. Taking combined mycelial pellet as the research object, its ability to treat papermaking wastewater, heavy metal wastewater and dye wastewater was investigated. The combined mycelial pellet was superior to the single fungal mycelium in the degradation of lignocellulose, removal of heavy metal ions and adsorption capacity of dyes. And the combined mycelial pellet has a wide range of application conditions (temperature range 28-34°C and pH range 4-8), which can maintain high processing capacity for papermaking wastewater, heavy metal wastewater and dye wastewater. After three batches of wastewater treatment, the combined mycelial pellet still maintains high activity and can continuously treat wastewater. The study fixed the single fungal mycelium together with cellulose-degrading bacteria, the strains producing different enzymes were combined to form a multi-functional combined mycelial pellet. This method provides a new way for industrial wastewater treatment.

Keywords: Dye, Heavy metal ions, Immobilized mycelial pellet, Lignin, Wastewater treatment

1. Introduction

A large amount of waste water and waste liquid are produced in the industrial production process, which is various in variety and complex in composition, and most industrial wastewater contains harmful toxic substances [1]. There are approximately 8.9 × 10⁵ tons of dye wastewater produced every year and the number of papermaking wastewater is over 2.7 × 10¹⁰ tons [2]. Japan's Minamata disease and bone pain events are important warnings for humans' neglect of industrial wastewater. For serious water pollution problems, wastewater treatment around the world is facing environmental, economic and political challenges. At present, wastewater treatment mainly includes physical methods, chemical methods and biological methods. With the increasing difficulty in the treatment of industrial wastewater, treatment of wastewater by physical or chemical methods alone is not suitable for the treatment of all current wastewater. For wastewater with complex composition, it usually contains refractory organic substances and toxic substances. Microbial method is usually used to treat these wastewater, which not only can effectively treat these industrial waste-waters, but also can greatly reduce the treatment cost of industrial wastewater [3, 4].

Fungi in submerged culture often grow in the form of compact spherical masses of mycelium known as pellets [5]. And it has the characteristics of not only strong metabolites ability and adsorption capacity of pollutants, but also has good biological activity, fast sedimentation rate and easy solid-liquid separation [6]. In recent years, mycelial pellet have been widely used as biosorbents in industrial wastewater treatment. Fujita et al. [7] have demonstrated that mycelial pellets formed by Aspergillus niger have good starch decomposition ability and TOC removal ability (more than 90% and 75%, respectively). In a continuously operating bioreactor, the selenite (SeO₃²⁻) in the synthetic wastewater is removed using a fungal bioreactor system containing Phanerochaete chrysosporium pellets [8]. Dong et al. [9] investigated the immobilizing fermentation characteristics and o-chlorophenol biodegradation of Rhodopseudomonas palustris using mycelial pellets as a biomass carrier.

However, the mycelial pellets prepared by a single strain still have limitations such as lower efficiency and single function, and...
the like. Therefore, in order to improve the degradation efficiency of refractory organic compounds and toxic pollutants, studies have focused on two or more kinds of fixed mycelium particles [10, 11]. Zhang et al. [12] studied the biological removal efficiency in the styrene butadiene rubber with combined mycelial pellet (Mycelial pellet of Aspergillus niger V3 and Acinetobacter calcoaceti-
cus JH-9). Louise and Geoffroy evaluated the biosorption of uranium (90%, 62%), strontium (44%, 39%) and caesium (41%, 50%) by pelleted mycelium of two species of fungi, Rhizopus arrhizus and Penicillium chrysogenum and immobilized Saccharomyces cere-
visiae was evaluated in both batch and continuous flow systems [13]. Lin Fanyu et al. [14] used marine xylose lysine Bacillus EZ008 to adsorb heavy metals Cd2+ (95.6%), Cr3+ (96.4%) and Cu2+ (87.0%) after 20 d. Lin et al. [15] used Aspergillus fumigatus (L-3) isolated from the soil as an immobilization carrier to immobilize Bacillus licheniformis to form an immobilized system, and studied its degra-
dation efficiency for Congo red. And the study showed that its degradation efficiency can reach more than 99%. Based on the screening of two marine fungi with lignocellulose degradation abil-
ity in the laboratory by Chen et al., a new type of two-strain immobil-
ization system-immobilized mycelium pellets was constructed and used in papermaking wastewater. According to research, the immo-
bilized mycelial pellet not only has a degrading efficiency of nearly 99% for papermaking wastewater. Moreover, the decolorization rate of Azure Blue B reached 69.7%, which was 1.6 times that of a single mycelium [16]. However, there are few preliminary studies on the immobilization of bacteria by fungi to form composite mycelial pellets and the treatment of papermaking wastewater.

In this paper, a mycelium pellet was prepared with mixture of a lignin-degrading Aspergillus acting as a biological carrier and B. cereus that possesses the ability of cellulose degradation. The ability of cellulose and lignin degradation of the compound myceli-
num pellet GX-1310 was evaluated. The effects of treatment condi-
tions (temperature, pH, incubation time) in papermaking waste-
water, heavy metal wastewater, and dye wastewater were systemati-
cally studied, to provide more technology choices for the various industry wastewater treatments [17].

2. Materials and Methods

2.1. Strain Sources

Aspergillus fumigatus G-13, which could degrade lignin used in this work was isolated from the samples collected from soil near the sewage draining exit of a paper mill in Harbin, China. Strain G-13 was identified as A. fumigatus by 18srDNA sequence analysis. The sequence is shown in the appendix.

Bacillus cereus X10-1-2 was isolated from the local soil by the laboratory of Green Chemical Technology of College of Helongjiang Province. The minimal medium contained (per liter): Na2HPO4 3.0 g, MgSO4·7H2O 0.5 g, CaCl2 0.5 g, MnSO4·7H2O 2.5 mg, ZnSO4 2.0 mg, CoCl2 3.0 mg, and FeSO4·7H2O 7.5 mg. Wheat bran [30 g/L] and bean cake (10 g/L) were added to supplement the minimal medium as the carbon source and nitrogen source for maximum cellulase production (unpublished date). After the bacteria were cultured in agarslantculture-medium at 30°C for 60 h, the B. cereus X10-1-2 was transferred to 4°C for storage.

2.2. Culture Medium

Mycelium pellet culture medium is made by sucrose 18 g/L, ammno-
rium tartrate 2.5 g/L, KH2PO4 2 g/L, MgSO4·7H2O 2 g/L in 1 L of distilled-deionized water (adjust pH to 5, autoclave under 120°C for 20 min).

Culture collection of bacteria is made by beef paste 5 g/L, peptone 10 g/L, NaCl 5 g/L, agar18 g/L in 1 L of distilled-deionized water (adjust pH to 7.2-7.4, autoclave under 120°C for 20 min.)

2.3. Simulated Industrial Wastewater

Simulated papermaking wastewater is prepared by straw 100 g (dry weight), NaOH 20 g, anthraquinone 0.5 g, Na2S 0.795 g, in 580 mL of distilled-deionized water (heat up to 125°C and insulate for 20 min).

Simulated heavy metal wastewater is prepared by CuSO4 79.93 mg or Pb (NO3)2 195.32 mg in 1 L of distilled-deionized water (autoclave under 120°C for 20 min).

Simulated dye wastewater is prepared by congo red 100 mg, malachite green 100 mg, and crystal violet 100 mg, respectively, in 1 L of distilled-deionized water (autoclave under 120°C for 20 min).

2.4. Preparation of Fungal or Bacterial Suspension

Colonies of Aspergillus and B. cereus were collected from inclined medium, and then added with normal saline, the concentration of which was 1 × 107/mL and 5 × 109/mL, respectively, and stored at 4°C.

2.5. Preparation of Mycelial Pellet

2.5.1. Preparation of mycelial pellet of single fungi

Took 5 mL of A. fumigatus G-13 suspension into the optimized spheroidized culture medium (The carbon source is 18 g/L sucrose, the nitrogen source is 2.5 g/L ammonium tartrate, and initial pH of the medium is 5). The culture temperature was 30°C, the oscillator speed was 160 r/min, and the culture was carried out for 72 h. Under these conditions, the average diameter of mycelial pellet was the largest, about 3.4 mm. The mycelial pellet at this time has a smooth surface and good elasticity, and is suitable as a bio-im-
mobilized carrier. Collected the mycelial pellets by filtration and placed in sterile physiological saline for use.

2.5.2. Preparation of combined mycelial pellets

The inoculation amount of B. cereus X10-1-2 is 20 mL (100 mL medium), the pH of medium is 5, the shaking speed is 160 r/min, and the temperature is 28°C. Under these conditions, X10-1-2 and G-13 have the best complementarity in the co-fixation process. The two-species immobilization mycelial pellet play a synergistic role in enzyme production process, promoting the secretion of lignin degrading enzymes, cellulase and hemicellulase. Took 5 mL of G-13 suspension and 20 mL of X10-1-2 suspension into the optimized spheroidized culture medium. The culture temper-
ature was 30°C, the oscillator speed was 160 r/min, and cultivated for 72 h. Collected the mycelial pellets by filtration and placed in sterile physiological saline for use.
2.6. Papermaking Wastewater Treatment Experiments

Took 0.1 g of the sample to be tested, added 5 mL of acetic acid-nitric acid mixed solution (10 mL of concentrated HNO₃ and 100 mL of 80% acetic acid), heated in a boiling water bath for 20 min, cool and filter. Took 1 mL of the filtrate, added 4 mL of lichenol reagent, held at 100°C for 15 min, and measured the OD value at 660 nm. According to the standard curve of xylene, the amount of sugar was calculated, and then multiplied by a coefficient of 0.9, which was the content of hemicellulose. The residue obtained by filtration was washed twice with acetone, dried to constant weight at 60°C, placed in a beaker, added with 5 mL of 72% sulfuric acid, hydrolyzed at 20°C for 3 h, added with water 45 mL, stayed overnight at room temperature and filter the next day. Took 2 mL of the filtrate, added 5 mL of anthrone reagent, held at 100°C for 10 min, and measured the OD value at 660 nm. According to the standard curve of glucose, the amount of sugar was calculated, and then multiplied by a coefficient of 0.9, which was the content of cellulose. The residue obtained by filtration was dried to constant weight at 80°C, weighed and then ashed at 550°C, the obtained mass was lignin content [18].

Mixed suspension 5 mL was inoculated on 100 mL of the 1:4 dilution of simulation papermaking wastewater after sterilized (160 r/min and 28°C). In contrast, the control group was not treated by mycelial pellet under the same conditions. Regularly samples and analysis the lignocellulose content in the culture. To determine the lignocellulose degradation ability of two-species immobilized mycelial pellet, the contents of lignin, cellulose, and hemicellulose were analyzed.

Degradation efficiencies of lignin, cellulose or hemicellulose at the nth day (Dₙ) were calculated by the following formula:

\[ Dₙ = \frac{mₚₙ - mₚₙ}{mₚ} \times 100 \% \]  \hspace{1cm} (1)

Where \( mₚ \) and \( mₚₙ \) represent the total amount of lignin, cellulose or hemicellulose in fermentation substrate at the previous sampling time and that at the nth day (DR), respectively.

2.7. Simulated Heavy Metal Wastewater Treatment Experiments

5 mL of the mixed suspension was inoculated into 250 mL Erlenmeyer flask containing 100 mL of simulated heavy metal wastewater. Cultured in an oscillator at 28°C and 160 r/min and sampled regularly. The supernatant (centrifuged at 6,000 r/min for 10 min) and absorbance at the maximum absorption wavelength of each dye was measured with an ultraviolet-visible spectrophotometer. The absorbance of the dye culture solution which was not inoculated with the hyphae sphere was used as a control, and calculated the decolorization rate. All the experiments were performed in triplicate. The dye decolorization rate (Cₙ) calculated by the following equation:

\[ Cₙ = \frac{aₙ - a_p}{a_p} \times 100 \% \]  \hspace{1cm} (3)

Where \( aₙ \) is the dye absorbance of the control and \( a_p \) is the dye absorbance of the samples.

3. Results and Discussion

3.1. Morphology of Combined Mycelial Pellets

Fig. 1 (a) is a combined mycelial pellet formed under the optimum bailing conditions screened by previous experiments. The formed mycelial pellet is white, uniform in size (average diameter of about 4.35 mm), smooth in surface and has certain mechanical strength. Fig. 1 (b) shows the internal structure observed by scanning electron microscopy after cutting the mycelial pellet. The large number of interlaced filaments seen in Fig. 1 (b) are hyphae produced by Aspergillus fumigatus. Because the bacteria of Bacillus cereus used in this study are rod-shaped, the size is 1-1.2*3-5um, at this magnification, we can see a large number of small bright spots on the hyphae that are the bacteria of Bacillus. As shown in the SEM images, a large number of bacteria were found in the inner space of mycelial pellet, X10-1-2 bacteria were successfully immobilized on the G-13 mycelia, suggesting that the pellet’s polyporous structure provides sufficient surface area for the adhesion of X10-1-2 bacteria and to establish a microecological environment suitable for bacterial growth [20]. The mycelial pellet is formed by winding mycelium, and has a spatial network structure inside, which has the characteristics of porous and large surface area. It indicates that the combined mycelial pellet can be used as a biomass carrier to meet the needs of treating wastewater.

3.2. Capability Comparison between the Single-strain Mycelial Pellet and Two-species Immobilized Mycelial Pellet GX-1310

5 g of single-strain mycelial pellet and 5 g of two-species immobilization mycelial pellet were respectively introduced into simulated papermaking wastewater, dye wastewater and heavy wastewater. Table S1 shows the difference in degradation efficiency between the single-strain and two-species immobilization mycelial pellet GX-1310 under the same culture conditions. Generally, the processing efficiency does appear significantly different. The combined
Mycelial Pellets are better for treatment of papermaking wastewater. The degradation rate of lignin (L) increased by more than 10%, and the degradation rate of cellulose (C) and hemicellulose (H) increased by more than 30%. This is due to the fact that mycelial pellet fixes the \textit{B. cereus}, which confers the ability of the combined mycelial pellets to degrade cellulose and hemicellulose. Compound mycelium plays a synergistic role in the process of enzyme production, thereby increasing the degradation rate of lignocellulose. For the treatment of other wastewater, it is first reported in the literature that both \textit{Aspergillus fumigatus} \cite{21,22} and \textit{Bacillus} \cite{23,24} have adsorption capacity for pollutants (dye wastewater and heavy metal ions). Secondly, their adsorption of pollutants may be a process of biological adsorption \cite{21,22,24}. Therefore, the composite mycelial pellets may act through the active sites on the surface during the adsorption process. In addition, biosorption is related to the surface area of the organism. The larger the surface area of the organism, the stronger the adsorption capacity. The interior of the mycelial pellets of \textit{Aspergillus fumigatus} shows a spatial network structure. With the fixation of \textit{Bacillus}, the surface area of mycelial pellets increases, so the adsorption capacity of composite mycelium pellets for pollutants is significantly greater than that of single mycelium pellets for pollutants. For the treatment of dye wastewater, the decolorization rates of Congo red (CR), malachite green (MG) and crystal violet (CV) by single fungal mycelium were 69.51%, 71.13% and 62.33%, respectively. The decolorization rates of the above three kinds of dyes by the combined mycelial pellets were 92.74%, 91.61% and 84.23%, respectively. For the adsorption of heavy metal ions, the adsorption rates of Cu\textsuperscript{2+} and Pb\textsuperscript{2+} by single fungal mycelium spheres were 38.27% and 34.06%, respectively. The adsorption rates of Cu\textsuperscript{2+} and Pb\textsuperscript{2+} by the combined mycelial pellets were 65.96% and 52.33%, respectively. It is concluded that the performance of the two-species immobilization mycelial pellet is superior to that of the single-strain mycelial pellet for the degradation and adsorption of various wastewaters.

3.3. GX-1310 Treatment Experiments of Papermaking Wastewater

3.3.1. Effect of temperature on degradation of lignocellulose

The water was sampled at an interval of 2 d and tested the maximum degradation rate of lignocellulose under different temperatures to study the effect of temperature \cite{25}. As elucidated in Fig. 2, the optimum temperature range was 28-34\(^{\circ}\)C of GX-1310. Lignin degradation rate got highest at 28\(^{\circ}\)C up to 58.01%. However, the degradation rate of cellulose and hemicellulose reached the highest, as high as 45.39% and 57.45% when the temperature was 30\(^{\circ}\)C and 34\(^{\circ}\)C, respectively. The degradation rate of the three was 31.53%, 21.55% and 27.52% at 24\(^{\circ}\)C, and even if the temperature raised to 40\(^{\circ}\)C, degradation rate still reached up to 32.80%, 36.09% and 37.91%. And our previous research found that the composite mycelial pellets have low enzyme activity at low temperatures. When the temperature is 28\(^{\circ}\)C, the lignin degrading enzyme activity reaches the maximum, and when the temperature is 30\(^{\circ}\)C, the cellulase activity reaches the maximum. At 34\(^{\circ}\)C, the hemicellulase activity reaches its maximum \cite{26}. This is because different components are affected by different enzymes, so the required temperature is different. Even if a small number of enzymes have multiple repeated degradation functions, the most suitable temperature for...
each enzyme is also different. Results show that GX-1310 has good degradation effect on papermaking wastewater in the high temperature environment so as to be applied to a wide range of temperature [27]. Since in the existing literature, no matter whether it is a single bacteria (G-13 or X10-1-2) or a double bacteria (GX-1310), there is no report of papermaking wastewater treatment. We can say that this is the first time to study it. However, this removal efficiency is not very high at present and needs to be further improved.

3.3.2. Effect of pH on degradation of lignocellulose

Degradation of papermaking wastewater can be significantly influenced by initial pH of solution. As illuminated in Fig. S1, for lignin, the degradation rate was maximum at the initial pH 5, reaching 61.38%, however the data decreased to 14.01% and 12.09% respectively in either strong acid or alkali, which shows that the degradation of lignin can be intensely inhibited by strong acid and alkali, and the reason may be that the environment will inhibit the production of lignin-degrading enzymes, which is harmful to the degradation of lignin in papermaking wastewater [28]. Our previous studies have shown that when pH value is less than 3 or greater than 8, composite mycelium pellets do not form, indicating that strong acid and strong base inhibit the survival of composite mycelium pellets. It is pelletized and produces enzymatic activity when pH is between 3 and 7. Under the pH 5 condition, the enzyme activity of composite mycelium pellets was the highest, and the pellet formation state was the best [30]. In addition, it is very coincidental that both Bacillus (X10-1-2) and Aspergillus fumigatus (G-13) produced the highest enzyme activity at pH 5 [29, 30]. This coincidence provides a very favorable condition for the survival of the two bacteria at pH 5, so that the bacteria can simultaneously exert the ability to produce the highest enzyme activity. But the rates of other two lignocellulose as the initial pH was increased from 2 to 7, the degradation rate kept increasing, peaked at over 50%, then started to decline. The rate of cellulose and hemicellulose in papermaking wastewater at pH value from 5 to 11 could be maintained at more than 40%. All these results indicated that even in acidic or alkaline environment, GX-1310 could still keep efficient for long time. This indicates that the combined mycelial pellets could be used repeatedly to treat papermaking wastewater, however lignin degradation capability still need to be improved [31].

3.3.3. Effect of incubation time on degradation of lignocellulose

As expounded in Fig. 3, GX-1310 degradation rate of lignin showed a rise first followed by a decline with incubation time, as lignin is mainly composed of acid-soluble lignin macromolecules and small molecules of acid insoluble lignin composition. In the beginning, acid soluble part was degraded, the molecular system of lignin fragments gradually decreased, the degradation rate increased gradually and reached the highest at 144 h, was 63.61%. Therefore, in the process of degradation, pellets degraded large molecular fragments of acid-soluble lignin into small molecules of acid insoluble lignin, as a result, the system of acid-insoluble lignin content increased along with lignin degradation rate decreased. GX-1310 also has a very high ability of degradation of cellulose and hemicellulose, the highest degradation rates were 49.05% at 72 h and 63.36% at 60 h, respectively. At 90 h, according to enzyme catalysis kinetics, the enzyme is saturated with substrates. So after 90 h, the degradation efficiency of composite MYCELLIUM pellets for cellulose and hemicellulosic tended to be basically stable. Therefore, with the extension of time, the degradation efficiency of cellulose and hemicellulose is stable at about 60% and about 45%, respectively.

3.3.4. Effect of recycle on degradation of lignocellulose

For the investigation of the stability of GX-1310 and its reuse effect, the culture was shocked at 160 r/min and 28 °C for 5 d, and this process was repeated four times, the results are shown in Table S2. At the first time, lignocellulose degradation was pretty good, and degradation rates of lignin, cellulose and hemicellulose were 51.27%, 41.58%, 57.1% respectively. With the increase of the frequency the fractions of lignocellulose degradation rate decreased, and at the third times, pellet surface was not smooth as originally with the color deepening, then degradation rate dropped gradually. But the degradation rate of all three kinds of lignocellulose could maintain more than 20%. Until the fourth cycle, the mycelium pellet began to appear autolysis phenomenon. The results revealed that GX-1310 can be used three times and retain high activity for long time. This indicates that the combined mycelial pellets could be used repeatedly to treat papermaking wastewater, and the activity could be maintained for a relatively long time.

3.4. GX-1310 Adsorption Experiments of Heavy Metal Wastewater

3.4.1. Effect of temperature on adsorption of Cu$^{2+}$ and Pb$^{2+}$

Tested the maximum adsorption rate of Cu$^{2+}$ and Pb$^{2+}$ under different temperatures. The effects of temperature on the removal rates of heavy metal ions are shown in Fig. 4. [32]. The optimum temperature range was 28-34°C which was similar to papermaking wastewater. The percentages of Cu$^{2+}$ and Pb$^{2+}$ absorbed raised from approximately 20% to about 60% with temperature increasing. The biosorption rates of Cu$^{2+}$ increased up to 63.73% at 28°C, and Pb$^{2+}$ to 57.83% at 30°C, then began to decline. This is because we found in the previous study that under the condition of 28°C, the compound mycelial pellets are in the best growth state [30, 26]. However, adsorption was less effective at 20°C or 40°C. It
instructed that temperature can affect the adsorption of heavy metal roughly when the temperature exceeds the threshold temperature.

3.4.2. Effect of pH on adsorption of Cu$^{2+}$ and Pb$^{2+}$

pH is one of the most important parameters controlling uptake of heavy metals from wastewater. Fig. S2 shows the effect of pH on Cu$^{2+}$ and Pb$^{2+}$ removal efficiencies of compound mycelium pellets. As expected, the adsorptions of Cu$^{2+}$ and Pb$^{2+}$ are of high-efficiency in the neutral condition. The percentage adsorption increased with pH to attain a maximum at pH 5 and thereafter it decreased with further increasing in pH value. The maximum removal of Cu$^{2+}$ and Pb$^{2+}$ at pH 5 were found to be nearly 73.21% and 59.29%, respectively, which may be attributed to the fact that the proton occupied most of the adsorption sites on the surface of mycelial with lower pH. The adsorption percentage of heavy metal ion was awfully effective with increasing of pH from 5 to 9. On the contrary, as the pH over 9, the OH$^-$ in solution would combine with functional groups on the surface of mycelium pellets, which may be competition with metal ions, and then lead to the adsorption rate decreased. Cu$^{2+}$ (> 75 %) was removed more efficiently than Pb$^{2+}$, and similar results was also reported by Chrysi and Papadimitriou. Moreover, it should be underlined that adsorption of Pb$^{2+}$ was sensitive to pH than Cu$^{2+}$. With pH increasing to appropriate, the number of Cu$^{2+}$ doubled while the data of Pb$^{2+}$ magnified almost three times. The results put on view that this kind of pellet has a good adsorption effect on heavy metal ions in neutral and acidic environment.

3.4.3. Effect of incubation time on adsorption of Cu$^{2+}$ and Pb$^{2+}$

The water was sampled at an interval of 30 min and then tested. The influence of incubation time on the adsorption of metal ions (Cu$^{2+}$, Pb$^{2+}$) was studied and results obtained are represented in Fig. 5, adsorption of Cu$^{2+}$ and Pb$^{2+}$ achieved 51.27% and 31.65%, respectively in a quite short period of time, just in 2 h. The concentration of heavy metal ions decreased rapidly since complexation of active groups with heavy metal ions on the cell wall was quite rapid during this state of surface adsorption. After that, as time increasing, concentration of heavy metal ions in solution decreased slowly until adsorption equilibrium, which could be explained as adsorption of heavy metal ions on the cell wall reached saturation with the increase of adsorption amount, and the resistance would be increased as metal ions entered cells, so that the adsorption reached saturation for a long time. Adsorption rate of Cu$^{2+}$ and Pb$^{2+}$ reached the maximum, 76.96% and 61.32% in 48 h and 72 h, respectively.

3.5. GX-1310 Treatment Experiments of Dye Wastewater

3.5.1. Effect of temperature on congo red, malachite green and crystal violet decolorization

The result of temperature studies for the adsorption of congo red, malachite green and crystal violet at different temperatures are given in Fig. 6, the effect on dye was not significant when the temperature varied from 24 to 34°C. The reason is that too high (38°C) or too low temperature (26°C) can lead to the decrease of biomass. We found that decolorization rate of malachite green and crystal violet was lower than that of congo red. The maximum
malachite green and congo red removal rate reached 94.75% and 96.43% at 28°C. And crystal violet peak as 81.63% at 30°C. When the temperature reached 40 °C, decolorization rate of all three dyes was about 30%. It can be inferred that the extreme temperature will reduce decolorization rate of GX-1310.

3.5.2. Effect of pH on congo red, malachite green and crystal violet decolorization

Removal of dyes from aqueous solutions at different pH and temperatures by GX-1310 has been carried out successfully. As shown in Fig. S3, with increasing of pH from 2 to 7, the percentage of the dye adsorbed by pellets increased from 55% to 98%, 30% to 92% and 45% to 70% for congo red, malachite green and crystal violet, respectively, which shows that removal of pollutants from wastewater by adsorption is greatly influenced by the pH of solution. By affecting the surface charge of the adsorbent and the extent of ionization, consequently, the rate of adsorption increased [34]. A change of pH affects the adsorptive process through dissociation of functional groups on the adsorbate and adsorbent. Dyes which ionize to give the colored cationic dye base will undergo attraction approaching the anionic structure of the adsorbents. Decolorization rates of three dyes were as high as 70% at pH of 5-9. The maximum decolorization of congo red and malachite green can reach 97.67% and 94.55% at pH 5. While decolorization ability of crystal violet was peaked at 83.67% at PH 7. The results show that the adsorption of dyes could be of great efficiency in weak acidic and alkaline system. However, similar to the effect of temperature, congo red is less sensitive to pH among the three dyes.

3.5.3. Effect of incubation time on congo red, malachite green and crystal violet decolorization

As seen in Fig. 7, the adsorption amount of the three kinds of dyes by combined mycelial pellets increased very rapidly within 2 h, and then gradually slowed down until the adsorption equilibrium. For the three dyes of congo red, malachite green and crystal violet dyes, the decolorization rate could reach more than 70% in the first 12 h, and the decolorization rate was faster. The decolorization of congo red was faster and more efficient at the first 6 h [34], reached the highest as 97.92%. The adsorption equilibrium of malachite green and crystal violet can be easily reached within 24 h and 48 h respectively with a decolorization rate of 61% and 88.63%. The results showed that the combined mycelial pellets GX-1310 had good decolorization effect on all three dyes in a short time.

4. Conclusions

It can be seen from the above results that the composite mycelium pellets constructed in this study can not only treat heavy metal ion wastewater and dye wastewater, but also treat papermaking wastewater. As there are many research reports on the adsorption of dye wastewater and heavy metal ion wastewater by biological bacteria, these have been explained in the introduction. However, there are few previous studies on the fixation of bacteria (X10-1-2) by fungi (G-13) to form composite mycelium pellets and the treatment of papermaking wastewater, we are the first to study this. The results showed that the composite mycelium pellets could degrade papermaking wastewater efficiently. In addition, the composite mycelium pellets can be considered as a new and effective two-strain system capable of removing multiple pollutants, which can provide a new research direction for the removal of multiple pollutants by biological bacteria in the future.

Wastewater treatment by combined mycelial pellets showed a superior performance because of synergies effect on recombination process. The present study showed that two-species immobilized mycelia pellet GX-1310 could be reused to treat papermaking wastewater. As the degradation rate of lignin, cellulose and hemicellulose could maintain more than 20% even if after treating for the third process, which indicates that GX-1310 can be applied in continuous wastewater treatment process for a long-time activity maintenance. In addition, GX-1310 can also be tolerant to relatively high temperatures and strong basic systems. In the high-temperature environment, GX-1310 could maintain high activities during papermaking wastewater treatment process. GX-1310 also has favorable treatment effects on all these three types of wastewater. The rate of decolorization of dyes surpasses 70% even if when pH is 9. Moreover, GX-1310 is biodegraded and bioabsorbed highly tolerant and efficacious, therefore which has comprehensive application in the fields of polluted water treatments.

Author Contributions

G.W. (M.S. Student) and F.Q. (M.S. Student) conducted all the experiments. G.G.J. (M.S. Student) and L.J.D. (M.S. Student) prepared the manuscript. D.X. (Miss) checked the grammar of the article. Y.H. (Professor) performed data analysis and supported in the manuscript preparation.
