Heavily doped \( \text{Ba}_{1-x} \text{K}_x \text{Mn}_2 \text{As}_2 \) (\( x = 0.19 \) and \( 0.26 \)) single crystals were successfully grown, and investigated by the measurements of resistivity and anisotropic magnetization. In contrast to the antiferromagnetic insulating ground state of the undoped \( \text{BaMn}_2 \text{As}_2 \), the K-doped crystals show metallic conduction with weak ferromagnetism below \( \sim 50 \) K and Curie-Weiss-like in-plane magnetic susceptibility above \( \sim 50 \) K. Under high pressures up to 6 GPa, the low-temperature metallicity changes into a state characterized by a Kondo-like resistivity minimum. Electronic structure calculations for \( x = 0.25 \) using \( 2 \times 2 \times 1 \) supercell reproduce the hole-doped metallic state. The density of states at Fermi energy have significant As \( 4p \) components, suggesting that the \( 4p \) holes are mainly responsible for the metallic conduction. Our results suggest that the interplay between itinerant \( 4p \) holes and local \( 3d \) moments are mostly responsible for the novel metallic state.

I. INTRODUCTION

The discovery of Fe-based pnictide superconductors\(^1,2\) has also brought considerable research interest on the isostructural pnictides containing other transition metals, like \( \text{LaT}_2 \text{MAsO} \) and \( \text{BaT}_2 \text{M}_2 \text{As}_2 \) (\( T_M \) stands for 3d transition metals such as Mn, Fe, Co and Ni). Among them, the Mn-based materials are particularly worthy of investigation, because they exhibit antiferromagnetic (AFM) insulating ground state, similar to the parent compounds of high-\( T_c \) cuprates and colossal magnetoresistance manganites. According to the paradigm of metal-insulator transition\(^1,2\), it is expected to realize an insulator-to-metal transition either by charge carrier doping (band filling control) or by applying high pressures (band-width control) in the Mn-based pnictides. Very recently Tokura and co-workers\(^4\) indeed observed this kind of transition via electron doping in oxygen-deficient \( \text{SmMnAsO}_{1.5} \). Coincidentally we realized the metallization by hole doping in \( \text{La}_{1-x} \text{Sr}_{x} \text{MnAsO} \). Notably the metallic \( \text{La}_{0.8} \text{Sr}_{0.2} \text{MnAsO} \) polycrystalline sample showed an unusually large Seebeck coefficient of \( \sim 240 \mu \text{V/K} \).

Although the \( \text{BaT}_2 \text{M}_2 \text{As}_2 \) family all crystallize in elongated \( \text{ThCr}_2 \text{Si}_2 \)-type structure, they show diverse physical properties. \( \text{BaFe}_2 \text{As}_2 \) is a striped AFM semimetal with an ordered moment \( \sim 0.9 \mu_B/\text{Fe} \) serving as a prototype parent compound of Fe-based superconductors.\(^2\) \( \text{Ba}_2 \text{Cr}_2 \text{As}_2 \) was found to be a \( G \)-type AFM metal with an ordered moment \( \sim 2 \mu_B/\text{Cr} \) and with strong Cr \( 3d-\text{As} \) \( 4p \) hybridization.\(^5\) \( \text{BaCo}_2 \text{As}_2 \) exhibits a renormalized paramagnetic metal in proximity to a possible ferromagnetic quantum critical point.\(^6\) \( \text{BaNi}_2 \text{As}_2 \) was demonstrated as a fully-gapped superconductor.\(^7\) It seems that the count of \( 3d \) electrons determines the physical properties, and the metallic states can be understood by the partial filling of \( 3d \) electrons. Exceptionally \( \text{BaMn}_2 \text{As}_2 \) has a \( G \)-type AFM insulating ground state with a large moment \( \sim 3.9 \mu_B/\text{Mn} \) and a high Néel temperature \( \sim 260 \) K. The magnetic properties can be well described by the \( J_1 - J_2 - J \) Heisenberg exchange model.\(^8\)

The unique insulating property of \( \text{BaMn}_2 \text{As}_2 \) makes it promising to explore novel states of matter via applying high pressures as well as various chemical doping just like those\(^7,9,10\) employed in \( \text{BaFe}_2 \text{As}_2 \). Some doping studies\(^11,12\) were recently performed in \( \text{BaMn}_2 \text{As}_2 \) system. For the Mn-site doping,\(^13\) unfortunately, many transition metals do not substitute for Mn at levels above 0.5%. Although Cr and Fe (Mn's neighbors in the Periodic Table) can substitute for Mn significantly (at levels above 20\%), some dopants like La\(^14\) and Sr\(^15\) succeeded in doping small amount of K (1.6% in single crystals and 5% in polycrystals) into \( \text{BaMn}_2 \text{As}_2 \). They demonstrated that the K doping induced hole carriers, and changed the system into a metallic state. Interestingly the local moment of Mn as well as the Néel temperature is basically preserved against the K doping. It was thus advocated that the newly developed class of materials bridged the gap between the iron pnictide and cuprate high \( T_c \) materials. Another recent study\(^16\) showed a pressure-induced metallization in \( \text{BaMn}_2 \text{As}_2 \).

Motivated by the hole-doping result in \( \text{LaMnAsO} \) we also succeeded in growing K-doped \( \text{BaMn}_2 \text{As}_2 \) single crystals.\(^17\) In this paper, we report the measurements of electrical resistivity, magnetoresistivity, anisotropic magnetization and heat capacity for the single crystals of heavily doped \( \text{Ba}_{1-x} \text{K}_x \text{Mn}_2 \text{As}_2 \) (BKMA) with \( x = 0.19 \) and 0.26. The samples show metallic behavior with the resistivity one order of magnitude smaller than previously reported\(^18\) in the lightly K-doped samples. Besides, a weak ferromagnetic transition was observed below \( \sim 50 \) K on the background of local-moment AFM order. Novel metallic state is also manifested by the Curie-Weiss-like in-plane magnetic susceptibility, and the appearance of a
minimum in low temperature resistivity under high pressures. Electronic structure calculations suggest that the interplay between itinerant As 4p holes and local Mn 3d moments plays an important role for the strange metallicity in BKMA system.

II. EXPERIMENTAL

Single crystals of BKMA were grown by high-temperature spontaneous nucleations using MnAs as the self flux. First, MnAs was prepared by reacting stoichiometric mixture of Mn and As powder at 1073 K for 16 hours in an evacuated quartz tube. Second, Ba and K pieces with the presynthesized MnAs powder were put into an alumina crucible in the molar ratios of (Ba+K):MnAs=1:5, and K:Ba=0 and 1. All the starting materials have the purity ≥99.9%. For the growth of K-doped crystals, the alumina crucible was placed into an iron tube sealed by an iron cap, in order to protect the potassium from reacting with quartz tube. All the procedures were conducted in a glove box filled with argon with the water and oxygen content below 0.1 ppm. The iron tube was slowly heated up to 1503 K holding for 8 hours in a furnace filled with protective argon atmosphere. Then it was allowed to cool down to 1323 K at a cooling rate of 5 K/h, followed by shutting off the furnace. Shiny black crystals with typical size of 2mm×2mm×0.1mm were obtained. The as-grown crystals were found to have two categories of K content. Those with higher K content (x=0.33~0.43) was inhomogeneous (e.g., they showed broad x-ray diffraction and multiple weak ferromagnetic transitions), so we will not discuss them in this paper. Others with lower K content (x=0.15~0.27) had homogeneous distribution of K. The two crystals studied here were from the second category, and they were carefully cleaved and selected to remove the flux MnAs as far as possible. Note that the crystals had been stored in a glove box free of oxygen and water at room temperature for 5 months.

X-ray diffraction was performed at room temperature using a D/Max-rA diffractometer with Cu Kα radiation and a graphite monochromator. As usual, the crystallographic c axis was found to be perpendicular to the crystal plate. Therefore, the lattice parameter c was able to be calculated by the (00l) multiple diffractions after making the zero shift correction. The content of the doped potassium in the single crystals were measured by energy-dispersive x-ray spectroscopy (EDS), equipped in a field-emission scanning electron microscope. The electrical resistivity was measured by a standard four-probe method. Gold wires were carefully attached to the crystal by using silver paint under an optical microscope. The error caused by the size of the electrodes leads to the total uncertainty in the absolute resistivity of 10%. Hydrostatic pressure was generated by a cubic anvil cell immersed in a cryostat. The magnetic property was measured on a commercial Quantum Design magnetic property measurement system (MPMS-5). The magnetization was measured under μ0H=1 T in the zero-field cooling mode.

The electronic structure calculations were based on density functional theory, using the CASTEP module of Materials Studio. The calculations employed ultrasoft pseudopotentials and a plane-wave expansion for the wave functions. The exchange correlation effects were treated by the generalized gradient approximation with the Perdew-Burke-Ernzerhof functional. The plane-wave basis energy cutoff was set at 330 eV. For the calculation of 25% K-doped BaMn2As2, a 2 × 2 × 1 supercell was built. From the experimental result, G-type AFM order was assumed to be the ground state. For bandstructure and density-of-states (DOS) calculations, 26 × 26 × 15 and 5 × 5 × 3 k-points were used, respectively.

III. RESULTS AND DISCUSSION

A. Sample Characterizations

The BKMA single crystals were characterized by XRD and EDS experiments. The typical EDS patterns for the
samples studied here, shown in the upper panels of Fig. 1, indicate the presence of only four elements K, Ba, Mn and As. The quantitative analysis gives the chemical formula as Ba_{0.81(3)}K_{0.19(1)}Mn_{2}As_{2} and Ba_{0.74(3)}K_{0.26(1)}Mn_{2}As_{2} for Sample A ($A$) and Sample B ($B$), respectively. The XRD patterns were recorded for the plate-like crystals placed horizontally on a sample holder. The diffraction peaks are very sharp with the full width at half maximum (FWHM) about 0.1°, indicating good homogeneity and crystallinity. They were indexed as (00l) reflections with l=even, consistent with the body-centered tetragonal structure (space group: $I4/mmm$). The crystallographic $c$ axes ($13.350\,$Å for $A$ and $13.330\,$Å for $B$) are 0.77% and 0.92% smaller than that of the undoped BaMn$_2$As$_2$ ($13.454\,$Å). This result is qualitatively consistent with those in previous reports. The absolute values of the resistivity $\rho$ at $T > 190\,$K is no less than 2 m$\Omega$ cm, which is over two orders of magnitude smaller than that reported in the high-temperature regime obey the non-adiabatic small-polaron transport model, respectively. The lower inset shows the low-temperature resistivity. The $K$ content of $A$ and $B$ is 0.19(1) and 0.26(1), respectively.

The fitted $\Delta$ value is 0.040 eV (using the $\rho(T)$ data from 60 K to 160 K). Note that $\Delta=\Delta_e + \Delta_{hop}$, therefore, the polaron-hopping potential $\Delta_{hop}$ is estimated to be 0.013 eV. This small-polaron transport behavior suggests that the dominant activated charge carriers are weakly localized instead of being itinerant in the parent compound. It is noted that neither thermally-activated model nor small-polaron one accounts for the low-temperature ($T < 60\,$K) data well. Instead the electrical transport tends to be dominated by variable range hopping (VRH) in the low-temperature regime, because the $\rho(T)$ data better fit the Mott’s law of three-dimensional VRH, i.e., $\rho \propto \exp(T_0/T)^{1/4}$.

In contrast to the semiconducting behavior above for undoped BaMn$_2$As$_2$ crystals, the K-doped crystals show metallic conduction in the whole temperature range, as shown in the lower panel of Fig. 2. The room-temperature resistivity is 2–3 m$\Omega$ cm, which is over two orders of magnitude smaller than that of BaMn$_2$As$_2$, and about one order of magnitude smaller than that reported for the lightly K-doped samples with $x=0.016$ and 0.05. This further confirms insulator-to-metal transition in BKMA. Below 1.5 K, $A$ with $x=0.19$ shows a tiny drop in resistivity. However, the resistivity of $B$ ($x=0.26$) exhibits an upturn below 2.8 K, like the well-known Kondo effect.

We chose the $x=0.19$ sample to study its pressure effect. Under high pressures, while the high-temperature resistivity decreases rapidly, the low-temperature resistivity decreases subtly. By careful examination, the low-temperature metallicity changes under pressures. At $P=2\,$GPa, the resistivity begins to increase with decreasing temperature below 10 K. This resistivity upturn is enhanced at higher pressures. Apparently, the pressure effect resembles that of the further K doping (see the above data of $x=0.26$). The result contrasts with the pressure-induced metallization in the parent compound BaMn$_2$As$_2$.22

B. Resistivity

Figure 2 shows the temperature dependence of electrical resistivity $[\rho(T)]$ of the undoped BaMn$_2$As$_2$ as well as the BKMA crystals. The $\rho(T)$ data of the parent material indicate semiconducting behavior with room-temperature resistivity of 430 m$\Omega$ cm. However, the temperature coefficient is positive (metallic-like) for $T > 190\,$K. This result is qualitatively consistent with those in previous reports. The absolute values of the resistivity are closer to those in Ref. 22. The data of 60 K $< T < 90\,$K can be well fitted with the standard thermally-activated equation, i.e., $\rho \propto \exp(E_g/k_B T)$. The fitted result gives the activation energy $E_g=0.027\,$eV, precisely coinciding with the previous report. This suggests that the bandgap $E_g$ is no less than $2E_a=0.054\,$eV, which agrees with the previous band calculation result ($E_g \sim 0.1\,$eV). We note that the $\rho(T)$ data in the high-temperature regime obey the non-adiabatic small-polaron transport behavior, i.e., $\rho \propto T^{3/2}\exp(\Delta/k_B T)$. The fitted $\Delta$ value is 0.040 eV (using the $\rho(T)$ data from 60 K to 160 K). Note that $\Delta=E_a + E_{hop}$, therefore, the polaron-hopping potential $E_{hop}$ is estimated to be 0.013 eV. This small-polaron transport behavior suggests that the dominant activated charge carriers are weakly localized instead of being itinerant in the parent compound. It is noted that neither thermally-activated model nor small-polaron one accounts for the low-temperature ($T < 60\,$K) data well. Instead the electrical transport tends to be dominated by variable range hopping (VRH) in the low-temperature regime, because the $\rho(T)$ data better fit the Mott’s law of three-dimensional VRH, i.e., $\rho \propto \exp(T_0/T)^{1/4}$.

We chose the $x=0.19$ sample to study its pressure effect. Under high pressures, while the high-temperature resistivity decreases rapidly, the low-temperature resistivity decreases subtly. By careful examination, the low-temperature metallicity changes under pressures. At $P=2\,$GPa, the resistivity begins to increase with decreasing temperature below 10 K. This resistivity upturn is enhanced at higher pressures. Apparently, the pressure effect resembles that of the further K doping (see the above data of $x=0.26$). The result contrasts with the pressure-induced metallization in the parent compound BaMn$_2$As$_2$.22

FIG. 2: (Color online) Temperature dependence of resistivity for BaMn$_2$As$_2$ (upper panel) and Ba$_{1-x}$K$_x$Mn$_2$As$_2$ (lower panel) crystals. The upper inset plots log $\rho$ and log($\rho/T^{3/2}$) against the reciprocal of temperature, corresponding to thermally-activated model and non-adiabatic small-polaron transport model, respectively. The lower inset shows the low-temperature resistivity. The K content of $A$ and $B$ is 0.19(1) and 0.26(1), respectively.
We note that the $\rho(T)$ data of $x=0.05$ sample can be fitted by a power law $\rho = \rho_0 + AT^n$ with $n=2$ in a wide temperature range. However, the present heavily-doped samples have a change in the power exponent below 50 K (see the upper panel of Fig. 4), which is associated with a weak ferromagnetic transition below. The change in $n$ from ~1.5 to ~2.5 can be explicitly seen in the series of plots with $T^n$ as the horizontal axes. The transition temperature tends to increase with increasing K-content or pressure.

C. Magnetization

Figure 5 shows the magnetic susceptibility ($\chi$) of the Ba$_{1-x}$K$_x$Fe$_2$As$_2$ single crystals. A remarkable magnetic anisotropy can be seen from the difference in $\chi_{ab}(T)$ and $\chi_c(T)$. The anisotropic ratio $\chi_{ab}/\chi_c$ is over 10 below 100 K (see the inset of figure 6), indicating the easy magnetization along the $ab$-plane. The inset of Fig. 5 shows the $\chi_c(T)$ data separately. The $\chi_c(T)$ data of both samples have a positive temperature coefficient at high temperatures (the low-temperature upturn seems to be related to the weak ferromagnetic transition to be discussed below). This phenomenon is similar to that of the lightly K-doped sample reported previously, which still has a G-type AFM ground state with the Mn-moment along the $c$-axis. The $\chi_c(T)$ behavior for $x=0.19$ and $x=0.26$ reflects that the Mn local moments, oriented along the $c$-axis, are antiferromagnetically ordered above room temperature. If so, $\chi_{ab}(T)$ should be almost temperature-independent, as it is for the parent compound, because the applied field is perpendicular to the ordered moments.

![Figure 3](image1.png)

**FIG. 3**: (Color online) Temperature dependence of resistivity for Ba$_{0.81}$K$_{0.19}$Mn$_2$As$_2$ under high pressures.

![Figure 4](image2.png)

**FIG. 4**: (Color online) Upper panel: derivative of resistivity in Ba$_{1-x}$K$_x$Mn$_2$As$_2$ ($x=0.19$ for A and $x=0.26$ for B) single crystals. Other panels: plots of resistivity versus $T^n$, indicating a change in the power exponent below ~50 K.

![Figure 5](image3.png)

**FIG. 5**: (Color online) Temperature dependence of anisotropic magnetic susceptibility for Ba$_{1-x}$K$_x$Mn$_2$As$_2$ single crystals. The inset displays a magnified view for $\chi_c(T)$ ($H||c$). The small sudden increase in $\chi$ of the sample of $x=0.26$ at 317 K is due to the presence of tiny amount (~0.01%) of ferromagnetic MnAs impurity.

\[ \chi_{ab}(T) = C \frac{T}{T+T_0} \]

\[ \chi_c(T) = C_0 \frac{T}{T+T_0} \]

\[ \chi(T) = \chi_{ab}(T) + \chi_c(T) \]

\[ \chi_{ab}(T) \propto \frac{T}{T+T_0} \]

\[ \chi_c(T) \propto \frac{T}{T+T_0} \]

\[ C = C_0 \]

\[ T_0 = T_0 \]

\[ A = A \]

\[ B = B \]

\[ x = x \]

\[ T = T \]

\[ n = n \]

\[ \rho = \rho \]

\[ \rho_0 = \rho_0 \]

\[ A = A \]

\[ B = B \]

\[ x = x \]

\[ T = T \]
However, the high-temperature $\chi_{ab}(T)$ data basically obeys Curie-Weiss law, as shown in Fig. 6. One has to ascribe this anomalous $\chi_{ab}(T)$ to the hole doping. This reminds us of the Curie-Weiss metallic state in Na$_2$CoO$_2$. By fitting the $\chi_{ab}(T)$ data with an extended Curie-Weiss formula, $\chi(T) = \chi_0 + C/(T - \theta)$, we obtained the effective moment of $1.81\mu_B$/Mn for $x=0.26$ ($x=0.19$), equivalent to a local spin-1/2 paramagnet. The $\theta$ value for $x=0.26$ is 32 K and $-47$ K for $x=0.19$. This result suggests a magnetic exchange crossover from antiferromagnetic to ferromagnetic, via tuning the potassium doping level.

When $T < 50$ K where the ratio $\chi_{ab}(T)/\chi_c(T)$ shows a peak, $\chi_{ab}$ increases rapidly, or $1/\chi_{ab}$ has a positive curvature for both samples, especially for $x=0.26$. This suggests a ferromagnetic component, which is confirmed by the $M_{ab} - H$ plot showing in Fig. 7. At the temperatures above 55 K, the magnetization increases linearly with the applied field. At low temperatures, however, the $M_{ab} - H$ data show a jump in magnetization. The saturated magnetization $M_{sat}$ is 0.02 $\mu_B$/Mn and 0.077 $\mu_B$/Mn for $x=0.19$ and $x=0.26$, respectively. A magnetic hysteresis in the $M_{ab} - H$ loop is clearly seen for $x=0.26$, further confirming the intrinsic weak ferromagnetism. Above 0.05 T, the isothermal magnetization increases almost linearly and very much slowly. Considered the large Mn local moment which is antiferromagnetically ordered above room temperature, this $M_{ab}(H)$ behavior suggests dominant local-moment antiferromagnetism. The $M_c - H$ curve at 3 K for the $x=0.26$ crystal shows tiny saturated magnetization of 0.005 $\mu_B$/Mn (not shown here). So, the spontaneous ferromagnetic moment is basically along the basal planes. The absence of magnetic hysteresis and smaller saturated magnetization for the sample of $x=0.19$ suggest that it is on the verge of the emergent ferromagnetism.

D. Electronic Structure Calculation

In order to understand the K-doping effect in BaMn$_2$As$_2$, we employed first-principles electronic structure calculations. The band structure of the undoped compound in Fig. 8(a) shows an indirect band gap of 0.11 eV, which is consistent with the results of above resistivity measurement and the previous calculations. The projected DOS indicates strong spin-dependent hybridization between Mn-3d and As-4p states, which explains the reduced moment of 3.8 $\mu_B$/Mn. The As-4p DOS can be better accounted for the difference between the total DOS and the Mn 3d projection. Thus, we conclude that, compared with the conduction bands, the valence bands have much more As-4p weight. In this regard, the parent compound can be considered as a charge-transfer insulator with strong Hund’s rule coupling.

By using supercell approximation, we were able to calculate the electronic structure of Ba$_{0.75}$K$_{0.25}$Mn$_2$As$_2$, which is very close to the case of Sample B. As shown in Fig. 8(b), though much more band dispersions appear near the Fermi energy due to the use of supercell, the main features are maintained (e.g., a bandgap of ~ 0.1 eV still appears above $E_F$), except that the Fermi level is shifted down by about 0.2 eV owing to the hole doping. The shift of $E_F$ makes multiple hole-like Fermi surfaces, which account for the metallic behavior in BKMA. Be-
cause As-4p holes usually have much higher mobility than the Mn-3d holes do, the metallic conductivity should be mainly contributed by the As-4p holes. Therefore, the anomalous resistivity minimum under pressures may be explained in terms of pressure-enhanced Kondo-like magnetic scattering of the conduction holes.

Except for the rigid band scenario, the main modification in the electronic structure of BKMA is that the As-4p weight at $E_F$ is reduced, suggesting that the K doping weakens the $p-d$ hybridizations. Consistent with the reduced hybridization, the calculated AFM local moment is significantly increased to 4.9 $\mu_B$/Mn, close to the value of a free Mn$^{2+}$ ion, and consistent with the previous neutron diffraction result (4.2 $\mu_B$/Mn for $x=0.05$).

Now let us briefly discuss the possible physics of the anomalous properties in BKMA. The weak ferromagnetism should be either local or itinerant. In the local case, the ferromagnetism is easily accounted for by the canting (toward the basal planes) of the Mn local moment. The mechanism could be like the double exchanges in manganites. Note that the saturation magnetization is much lower than the Mn local moment, therefore, such spin canting would be very slight. The second is an itinerant ferromagnetism scenario, in which the doped As 4p holes and/or Mn 3d holes are simply spin-polarized. In this case, the saturation magnetization should be comparable with the doping level per Mn ($x/2$), which basically agrees with the experimental saturation moment. The Curie-Weiss-like in-plane magnetic susceptibility resembles the behavior of Na$_x$CoO$_2$ ($x$ $\sim$0.7), as we pointed out above, suggests correlated metallicity in the present system. As for the resistivity minimum at high pressures, one has to consider the interactions between conduction holes and the local moments, but we have not arrived a definite picture so far. In a word, the interplay between itinerant 4p holes and local 3d moments seems to be very crucial. Future studies are called for to clarify all the novel properties shown in Ba$_{1-x}$K$_x$Mn$_2$As$_2$ system.

IV. CONCLUDING REMARKS

In summary, we have successfully synthesized heavily-doped Ba$_{1-x}$K$_x$Mn$_2$As$_2$ ($x=0.19$ and 0.26) single crystals which showed good homogeneity and crystallinity. By measuring the resistivity and magnetization, we confirmed metallization by a hole doping with potassium in BaMn$_2$As$_2$. Several anomalous properties in the metallic state were demonstrated. First, a weak ferromagnetic transition at $\sim$50 K was discovered. Second, the low-temperature resistivity behaves a Kondo-like minimum upon applying high pressures. Third, the in-plane magnetic susceptibility shows Curie-Weiss behavior, though being in an AFM state. Our electronic structure calculations indicate that the As 4p holes are most likely responsible for the metallic conduction. Therefore, these novel metallic behaviors reflect the interplay between itinerant 4p holes and local 3d moments in Ba$_{1-x}$K$_x$Mn$_2$As$_2$ system.

30 Unfortunately, our crystals are too small to make a reliable thermopower measurement. However, La$_{0.9}$Sr$_{0.1}$MnAsO indeed shows a very large thermopower at room temperature (Ref. 5).
