(Dated: December 30, 2011)

Abstract

A binary mixture of particles interacting via long-ranged repulsive forces is studied in gravity by computer simulation and theory. The more repulsive A-particles create a depletion zone of less repulsive B-particles around them reminiscent to a bubble. Applying Archimedes’ principle effectively to this bubble, an A-particle can be lifted in a fluid background of B-particles. This "depletion bubble" mechanism explains and predicts a brazil nut effect where the heavier A-particles float on top of the lighter B-particles. It also implies an effective attraction of an A-particle towards a hard container bottom wall which leads to boundary layering of A-particles. Additionally, we have studied a periodic inversion of gravity causing perpetual mutual penetration of the mixture in a slit geometry. In this nonequilibrium case of time-dependent gravity, the boundary layering persists. Our results are based on computer simulations and density functional theory of a two-dimensional binary mixture of colloidal repulsive dipoles. The predicted effects also occur for other long-ranged repulsive interactions and in three spatial dimensions. They are therefore verifiable in settling experiments on dipolar or charged colloidal mixtures as well as in charged granulates and dusty plasmas.

I. INTRODUCTION

Gravity or centrifugation is commonly used to sort and separate different particles out of a mixture but the underlying microscopic (i.e. particle resolved) processes of mixing and demixing under settling are still debated. It is known for long time that shaken or vibrated granular mixtures can exhibit the "brazil-nut effect", namely that the heavier particles are on top of the lighter ones. The details and parameter combinations for the brazil-nut effect to occur are still discussed. The brazil-nut effect may even contradict Archimedes’ law, which governs the equilibrium density profiles of molecular mixtures and colloidal solutions by the buoyancy principle.

Colloidal mixtures are valuable model systems to explore gravity effects on the particle scale both in equilibrium and nonequilibrium. Sediments of binary charged mixtures are commonly used to determine the phase behavior. In highly deionized charged colloidal mixtures, the sediment can split into separated layers due to counterion lifting, a phenomenon referred to as "colloidal brazil nut effect". The separation of binary hard-sphere mixtures was explored using the equation of state and separation of the two species was predicted in line with Archimedes’ principle. Recent experimental real-space studies on soft repulsive colloidal mixtures in three dimensions clearly showed that the buoyancy principle is not violated. Colloid-polymer mixtures are known to phase-separate under gravity in equilibrium.

Nonequilibrium studies, on the other hand, include the dynamics of the settling process on the particle scale after quickly turning the sample upside down, the enforcement of crystal growth on a patterned template under gravity, spatially varying temperature fields and novel zone formation in sedimenting colloidal mixtures. Interestingly, for colloidal mixtures, there are only few studies where gravity is changed periodically in time which may be considered to be the colloidal analogue of granulate shaking.

In this paper, we consider a binary mixture of particles interacting via long-ranged repulsive forces in gravity. We use Monte Carlo and Brownian dynamics computer simulation and mean-field density functional theory to predict the equilibrium density profiles and the nonequilibrium response of the system to oscillatory gravity. The more repulsive particles are referred to as A-particles while the less repulsive particles are the B-particles. A-particles create a depletion zone of small particles around them reminiscent to a bubble. Applying Archimedes’ principle effectively to this bubble, an A-particle can be lifted in a fluid background of B-particles. This "depletion bubble" mechanism results in a brazil nut effect where the heavier A-particles float on top of the lighter B-particles. It also implies an effective attraction of an A-particle towards a hard container bottom wall which produces a boundary layering of the A-particles. If the direction of gravity is periodically inverted causing perpetual mutual penetration of the mixture in a slit geometry, a similar stable layering emerges as a nonequilibrium phenomenon. We emphasize that our effects do not occur for short-ranged interactions like for hard sphere mixtures. This is only the case when the (effective) hard sphere interaction diameter differs largely from that of the actual particle size. Therefore, it is the softness of...
the repulsion which is relevant here.

Our results are obtained for a two-dimensional binary mixture of colloidal repulsive dipoles. Therefore, our simulation results can be verified in real-space microscopy experiments of two-dimensional superparamagnetic particles, see also for alternative set-ups. An external magnetic field induces repulsive dipole forces. The gravity can either be realized by tilting the droplets or by applying a laser light pressure on the sample. The predicted effects also occur for other long-ranged repulsive interactions and in three spatial dimensions. They are therefore verifiable in settling experiments on dipolar or charged colloidal mixtures as well as in charged granulates and dusty plasmas.

The paper is organized as follows: in section II, we describe the model and the simulation technique applied. In section III, we discuss the density functional theory. Results are presented in sections IV and V and we conclude in section VI.

II. MODEL AND SIMULATION TECHNIQUE

The system consists of a suspension of two species of point-like super-paramagnetic colloidal particles denoted as A and B, which are confined to a two-dimensional planar interface. These particles are characterized by different magnetic dipole moments $M_A$ and $M_B$, where

$$ M = M_B/M_A \tag{1} $$

is the dipole-strength ratio. The dipoles are induced by an external magnetic field $H$ according to $M_i = \chi_i H$ ($i = A, B$), where $\chi_i$ denotes the magnetic susceptibility. The magnetic field is applied perpendicular to the two-dimensional interface containing the particles. In the following, the dipole-strength ratio $M$ is fixed to 0.1, corresponding to recent experimental samples. The relative composition $X = N_B/(N_A + N_B)$ of B particles is fixed at 50%; hence we are considering an equimolar mixture. The particles are exposed to an external potential $V_{ext,i}(r)$ which is a combination of gravity and the hard wall, and is given by

$$ V_{ext,i}(r) = \begin{cases} m_i g y & \text{for } y \geq 0 \\ \infty & \text{otherwise} \end{cases} \tag{2} $$

Here, $m_i$ is the buoyant mass of particle species $i$ ($i = A, B$). Gravity acts along the $-y$ direction. We characterize the mass ratio by the dimensionless parameter

$$ m = m_B/m_A \tag{3} $$

The particles interact via a repulsive pair potential of two parallel dipoles of the form

$$ u_{ij}(r) = \frac{\mu_0}{4\pi} M_i M_j / r^3 = \frac{\mu_0}{4\pi} \chi_i H^2 / r^3 \quad (i, j = A, B), \tag{4} $$

where $r$ denotes the distance between two particles in the plane. For this inverse power potential, at fixed composition $X$ and susceptibility ratio $\chi_B/\chi_A$, all static quantities depend solely on a dimensionless interaction strength (or coupling constant)

$$ \Gamma = \frac{\mu_0 \chi_i^2 H^2}{4\pi k_B T_l A^3}, \tag{5} $$

where $k_B T$ is the thermal energy and $l_A = k_B T/(m_A g)$ the gravitational length of A particles, which we employ as a unit of length.

For time-dependent gravity ("shaking") we consider the external potential

$$ V_{ext,i}(r, t) = \begin{cases} m_i g(t) y & \text{for } 0 \leq y \leq L_y \\ \infty & \text{otherwise} \end{cases} \tag{6} $$

which embodies a time-dependent gravity strength $g(t)$ in a finite slit of width $L_y$. This is conveniently modelled to be a stepwise constant function of time:

$$ g(t) = \begin{cases} g & \text{for } n - 1 < t/T_0 \leq n - \vartheta \\ -g & \text{for } n - \vartheta < t/T_0 \leq n \end{cases} \tag{7} $$

$n = 1, 2, ..$ introducing a time period $T_0$ and a "swap fraction" $0 \leq \vartheta \leq 1$. Note that for the time-dependent gravity we confine the system to a slit of vertical width $L_y$ in order to keep the external potential bounded from below for all times.

The particle dynamics is assumed to be Brownian. Hydrodynamic interactions are neglected. The Brownian time scale is set by the short-time diffusion constant $D_A$ of the A-particles. Knowing that this diffusion constant scales with the inverse of the radius of a particle, $D_B$ was chosen such that $D_B/D_A = 1.61$ corresponding to the physical diameter ratio of the experimental samples.

We perform standard nonequilibrium Brownian dynamics (BD) and Monte Carlo (MC) computer simulations in the canonical ensemble where the particle numbers $N_i$ ($i = A, B$), the temperature $T$ and the area $A$ is fixed. In the static (equilibrium) case, where the external potential is not time-dependent, the one-particle density field has been calculated via MC simulations of $N_A = 600$ A-particles and $N_B = 600$ B-particles, which were placed in a finite rectangular box $L_x \times L_y$ of area $A = (30 \times 120)(l_A)^2$. In the nonequilibrium case, where gravity is time-dependent, we obtained the one-particle density field by performing BD simulations of $N_A = N_B = 300$ particles in a rectangular box of size $A = (15 \times 60)(l_A)^2$. In both cases, the simulation box features periodic boundary conditions in $x$-direction, an aspect ratio $L_x/L_y = 1/4$ and a gravitational load $N_A/L_x = 20/l_A$. The coupling constant $\Gamma$ is fixed to 10. A finite time step $\delta t = 10^{-4}T$ was used in the BD simulations, where $T = l_A^2/D_A$. We denote the density profiles as $\rho_i(r, t)$ ($i = A, B$) in the static case and $\rho_i(r, t)$ ($i = A, B$) in the dynamical case.
III. DENSITY FUNCTIONAL THEORY

Within density functional theory (DFT) the grand canonical free energy \( \Omega(T, \mu_A, \mu_B, [\rho_A(r), \rho_B(r)]) \) depending on the temperature \( T \) and the chemical potentials \( \mu_A, \mu_B \) is minimized with respect to the local particle one-particle densities \( \rho_A(r) \) and \( \rho_B(r) \). This functional can be split according to\( s^{52,55} \), so that in two spatial dimensions we obtain

\[
\Omega(T, \mu_A, \mu_B, [\rho_A(r), \rho_B(r)]) = \mathcal{F}_{\text{id}}([\rho_A(r), \rho_B(r)]) + \mathcal{F}_{\text{exc}}([\rho_A(r), \rho_B(r)]) + \sum_{i=A,B} \int d^2r \rho_i(r) \left[ V_{\text{ext},i}(r) - \mu_i \right],
\]

where the first term is the free energy of an ideal gas

\[
\mathcal{F}_{\text{id}} = k_B T \sum_{i=A,B} \int d^2r \rho_i(r) \left[ \ln(\Lambda_i^2 \rho_i(r)) - 1 \right]
\]

including the (irrelevant) thermal wavelength \( \Lambda_i \) of particles of species \( i (i = A, B) \). As already introduced above, \( V_{\text{ext},i}(r) \) is the static external potential acting on particle species \( i \). The only unknown part is the excess free energy functional \( \mathcal{F}_{\text{exc}} \), resulting from the inter-particle interactions. In order to approximate \( \mathcal{F}_{\text{exc}} \), we use a simple Onsager functional\( s^{56,57} \)

\[
\mathcal{F}_{\text{exc}} = \frac{k_B T}{2} \int d^2r \int d^2r' f_{ij}(|r - r'|) \rho_i(r) \rho_j(r'),
\]

consisting of the Mayer \( f \)-function

\[
f_{ij}(r) = 1 - e^{-\beta u_{ij}(r)},
\]

with the interaction potential \( u_{ij}(r) \) from equation\( s^{54} \) and the inverse temperature \( \beta = (k_B T)^{-1} \). The Onsager approximation is valid at low densities reproducing the second virial coefficient of the bulk fluid equation of state correctly but is expected to break down at higher densities. Unfortunately, unlike for hard-core interactions\( s^{56,59} \), no alternative approximation working at higher densities is known for soft inverse-power-law potentials\( s^{52} \). However, we expect the general trends to be captured by the theory but not the details of molecular layering.

The equilibrium density profiles \( \rho_i^{eq}(r) \) are obtained from the minimization condition

\[
\frac{\delta \Omega[\rho_A(r), \rho_B(r)]}{\delta \rho_i(r)} \bigg|_{\rho_i(r) = \rho_i^{eq}(r)} = 0.
\]

It is important to note that DFT is typically formulated in the grand-canonical ensemble where the chemical potentials \( \mu_A, \mu_B \) are fixed instead of the particle numbers, while the simulations are performed in the canonical ensemble. We have therefore considered the chemical potentials \( \mu_A, \mu_B \) as Lagrange multipliers which fix the total line density perpendicular to gravity and matched them such that this line density coincides with that prescribed in the simulations.

If gravity gets time-dependent, there is a dynamical generalization of DFT appropriate for Brownian systems which can be derived in various ways\( s^{60,61} \) from the exact Smoluchowski equation via an adiabatic approximation. Within this dynamical density functional theory (DDFT), the time-dependent density fields obey the generalized diffusion equation

\[
\frac{\partial \rho_i(r,t)}{\partial t} = \beta D_i \nabla \cdot \left( \rho_i(r,t) \nabla \frac{\delta \Omega[\rho_A(r,t), \rho_B(r,t)]}{\delta \rho_i(r,t)} \right),
\]

with a diffusion constant \( D_i \) corresponding to particle species \( i = A, B \). It is important to note that this equation conserves the total density, i.e. provided the starting density profiles are matched to that in the canonical ensemble, the time evolution given by the DDFT equation is canonical. Therefore, the results obtained from DDFT can directly be compared to our BD simulations. In our case of an external potential which depends only on the \( y \)-coordinate, we consider only density profiles which are independent of \( x \). This is justified far away from surface freezing\( s^{64} \).

IV. RESULTS IN EQUILIBRIUM

A. Colloidal brazil-nut effect

We performed MC simulations for various mass ratios \( 0 \leq m \leq 1 \) and dipolar ratios \( 0 \leq M \leq 1 \). Thereby, we choose \( A \) as the heavier and stronger coupled species\( s^{64} \). An example for the partial density profiles \( \rho_i^{eq}(r) (i = A, B) \) is given in Fig. 1 where at fixed \( M = 0.1 \) two different mass ratios \( m = 0.1, 0.5 \) are considered. Interestingly, the MC simulation data show quite distinct qualitative behavior for these two cases. In Fig. 1a \( (m = 0.1) \) the lighter \( B \)-particles are on top of the heavier \( A \)-particles as expected, while in Fig. 1b \( (m = 0.5) \) the behavior is reversed: here, the heavier \( A \)-particles are on top of the lighter \( B \)-particles. At first glance, this opposite trend is counterintuitive. We call it - in some analogy to granulate matter - (colloidal) brazil-nut effect.

DFT data are also included in Fig. 1. In fact, static density functional theory can basically reproduce the partial density profiles \( \rho_i^{eq}(r) (i = A, B) \) though the comparison is not quantitative since the functional is approximated by a low-density expression. In fact, as compared to the simulation data, the DFT results for the layering spacings are too large but the contact density of \( A \)-particles at the bottom wall are well reproduced in DFT (see the insets shown in Fig. 1). Of course, one should bear in mind that there is no fit parameter involved in the comparison.

In order to quantify the colloidal brazil-nut effect, we fol-
FIG. 1: (Color online) One-particle density profiles $\rho_{\text{eq}}^{i}(r)$, $i = A, B$ obtained from DFT and MC simulation. Mean sedimentation heights $h_{i}$, $i = A, B$ from Eqn. (14) are indicated by highlighted points for MC simulation data. a) $M = 0$, $m = 0.1$ (no brazil-nut effect). b) $M = 0.1$, $m = 0.5$ (brazil-nut effect). The insets enlarge the behavior at small wall distances where a strong peak of the $A$-particles occurs.

low the criterion proposed in Ref. 23. We define averaged heights $h_{i}$, $i = A, B$ by taking the first moment of the partial density fields as

$$h_{i} = \frac{\int_{0}^{\infty} y \rho_{\text{eq}}^{i}(y) dy}{\int_{0}^{\infty} \rho_{\text{eq}}^{i}(y) dy}, \quad i = A, B \quad (14)$$

In Fig. 1 the location of the corresponding heights are indicated by a large symbol. The brazil-nut effect is then defined by the condition

$$h_{A} < h_{B}, \quad (15)$$

which means that on average, the heavier $A$-particles are on top of the lighter $B$-particles. Within the full parameter range $0 \leq m \leq 1$, $0 \leq M \leq 1$, the region separating the brazil-nut effect from the ordinary behavior (no brazil-nut effect) is shown in Fig. 2. MC computer simulation data for the separation line are given by square symbols. These results were obtained by systematically scanning the parameter space. The brazil-nut effect occurs preferentially for strong dipolar asymmetry and is favoured if the two masses do not differ much. DFT results for the phase boundary are also included in Fig. 2 and are in good agreement with the simulation data predicting the same trends and the same slope of the separation line in the $M$-$m$ parameter space.

B. Depletion bubble picture

We now put forward an intuitive picture for the mechanism behind the colloidal brazil-nut effect which also provides a very simple theory for the separation line. This picture is based on the observation that when surrounded by a fluid of $B$-particles, a single $A$-particle creates a circular void-like space around it which is free of $B$-particles due to the strong repulsion between $A$- and $B$-particles, see the highlighted area in Fig. 3. This depletion bubble is firmly attached to the $A$-particle. Applying the buoyancy criterion to the whole bubble, the effective weight per area of the $A$-particles is strongly reduced. Assuming a homogeneous fluid density $\bar{\rho}_{B}$ surrounding a bubble of radius $R$ around an $A$-particle, the brazil-nut condition for lifting the $A$-particle can be stated as a buoyancy criterion

$$\frac{m_{A}}{\pi R^{2}} < m_{B} \bar{\rho}_{B} \quad (16)$$

We estimate the radius $R$ by a low-density argument, where the density profile of $B$-particles around an $A$-particle fixed at the origin is $\bar{\rho}_{B} \exp \left(-u_{AB}(r)/k_{B}T\right) = \bar{\rho}_{B} \exp \left(-M \Gamma \frac{1}{r^{3}}\right)$ such that a reasonable assumption for the radius $R$ of the depletion zone is given by the separation where the $AB$-interaction energy equals $k_{B}T$, i.e.

$$R = l_{A}(M \Gamma)^{1/3}. \quad (17)$$
Upon insertion in Eqn. (16), this yields the brazil-nut condition

\[ m > \left( \pi (MT)^2 \bar{\rho}_B^2 \right)^{-1} \]  

(18)

Thereby, a simple estimate for the separation line is provided. The only unknown parameter entering in Eqn. (18) is the averaged density \( \bar{\rho}_B \). We have used simulation data to determine \( \bar{\rho}_B \) as the effective density at a distance \( 2R \):

\[ \bar{\rho}_B = \rho_B^{eq}(2R) \]  

(19)

The resulting separation line is included in Fig. 2. Despite its simplicity, the depletion bubble picture describes the simulation data pretty well. Clearly, the depletion bubble is induced by the soft long ranged repulsion and is therefore missing for pure hard sphere mixtures where neighboring particles are at contact. However, when the interaction is mapped onto a substitute interaction core with an effective diameter \( \Gamma \), all the traditional sedimentation is qualitatively contained in this effective hard sphere mixture.

C. Boundary layering and effective interaction between an \( A \)-particle and the bottom wall

We finally discuss the implication of the depletion bubble on the layering of \( A \)-particles close to the hard bottom wall of the confining container (at \( y = 0 \)), see again the insets of Fig. 1. The strong layering is clearly demonstrated by an actual simulation snapshot shown in Fig. 4. If a single \( A \)-particle is fixed at a given distance from the bottom wall, its depletion bubble is reduced since the void space is cut by the hard wall, see the sketch in Fig. 5. Note that the \( A \)-particle is point-like so that in principle, it can approach the wall very closely. If the \( A \)-particle is close to the wall, the void space is half of the full circle in the bulk (situations I and III in Fig. 5). If the height \( y \) of the \( A \)-particles increases, the depletion bubble area \( A(y) \) grows. Assuming a constant depletion bubble radius \( R \), \( A(y) \) is given analytically as

\[ A(y) = R^2 \left\{ \frac{\pi - \arccos \left( \frac{y}{R} \right) + \frac{y}{R} \sqrt{1 - \left( \frac{y}{R} \right)^2}}{\pi} \right\} \]  

(20)

for \( y \leq R \) otherwise.

The growing bubble size causes two opposing effects: first, in order to increase the depletion bubble area, work against the osmotic pressure \( \bar{\rho}_B \) of the fluid \( B \)-particles is necessary. Assuming that \( \bar{\rho}_B \) is constant in the small height regime, this work equals \( \bar{\rho}_B (A(y) - A(0)) \) and gives rise to an effective attraction of an \( A \)-particle close to the wall (situation II in Fig. 5). In fact, this attraction is similar to the depletion attraction in the ordinary Asakura-Oosawa-Vrij model of colloid-polymer mixtures near a hard wall \( 67, 68 \) although there is a finite (physical) colloidal diameter in this model.

The second effect resulting from the increasing bubble size \( A(y) \) is a change in the effective buoyancy. The effective buoyant force is given by \( -m_{AB} + \bar{\rho}_B m_{BMg} A(y) \). If the bubble containing the \( A \)-particle is lighter than the surrounding \( B \)-fluid, this term is repulsive with respect to the wall and therefore opposed to the depletion force.

Combining these two effects, we gain the following analytical expression for the depletion potential \( V(y) \) between a single \( A \)-particle and the wall:

\[ V(y) = \begin{cases} 
\bar{\rho}_B (A(y) - \pi R^2/2) + m_{AB}gy & \text{for } y \geq 0 \\
-\bar{\rho}_B m_{BMg} \int_0^y dy' A(y') & \text{for } y < 0 
\end{cases} \]  

(21)
where the integral can be calculated as
\[
\int_0^y dy' A(y') = \pi R^2 y - R^2 y \arccos \left( \frac{y}{R} \right) \\
+ R^3 \sqrt{1 - \frac{y^2}{R^2}} - \frac{R^3}{3} \left(1 - \frac{y^2}{R^2}\right)^{\frac{3}{2}} \tag{22}
\]

This expression requires \( \bar{p}_B \) as an input parameter. In order to evaluate \( V(y) \), we have determined \( \bar{p}_B \) via a bulk reference simulation of a pure \( B \)-system (in the absence of gravity) at a prescribed number density \( \bar{\rho}_B \) by using the virial expression\(^{69}\).

We further checked a posteriori whether the radius \( R \) of the depletion bubble is consistent with that obtained from a radially averaged density profile of a bulk \( B \)-fluid around a single \( A \)-particle fixed at the origin. This "renormalized" radius \( R' \) can be estimated to be the position of the first inflection point in this density profile of \( B \)-particles (not shown here). Actually, we find values for \( R' \) which are a bit smaller than those given by the estimate \(^{17} \) which only works at low \( \bar{\rho}_B \).

More rigorously, we can define the effective interaction between the wall and an \( A \)-particle under the presence of the inhomogeneous distribution of \( B \)-particles by a potential of mean-force\(^{70,71} \). For a given altitude \( y \), the effective interaction potential \( V_{\text{eff}}(y) \) is given by
\[
V_{\text{eff}}(y) = - \int_0^y \langle F_A(y') \rangle \, dy', \tag{23}
\]

where \( \langle F_A(y) \rangle \) is the canonically averaged total force on the \( A \)-particle in the presence of the \( B \)-particles (which by symmetry points in the \( y \)-direction). \( F_A(y) \) also contains the trivial direct part \(-m_A g\) from gravity.

Computer simulation data for the effective potential \( V_{\text{eff}}(y) \) are presented in Fig. 6. Two possibilities occur:

if the \( A \)-particle is much heavier than the \( B \)-particles, the potential is fully attractive by a combination of depletion attraction close to the wall and gravity. In the brazil-nut case, on the other hand, there are three regimes in \( V_{\text{eff}}(y) \): an attractive regime close to the wall (corresponding to situation III in Fig. 5), followed by a repulsive regime (situation III in Fig. 5) and a subsequent attractive regime (situation IV in Fig. 5). The repulsive regime is caused by the lift force also responsible for the brazil-
V. RESULTS UNDER TIME-DEPENDENT GRAVITY (COLLOIDAL SHAKING)

Finally, we turn to the nonequilibrium situation of time-dependent gravity, see Eqn. \([21]\) which is a simple model of colloidal shaking. As far as our methods are concerned, we now use Brownian dynamics simulations appropriate for colloids and dynamical density functional theory. Various different starting configurations were used in the simulations to obtain statistical averages which were all sampled from an interacting bulk system. This corresponds to an initial homogeneous density field in DDFT. The swap fraction \(\vartheta\) is chosen to be 1/4, i.e. we consider the case that the time-average of the gravity is non-zero. In particular, we discuss the emergence of a steady state upon time-periodic gravity.

The relaxation of an initially homogeneous (but interacting) fluid of \(A\)- and \(B\)-particles towards its periodic steady state can be monitored by observing the instantaneous ensemble-averaged total potential energy \(E_{\text{pot}}\) of the system:

\[
E_{\text{pot}}(t) = \frac{1}{2} \int \mathrm{d}^2 r \int \mathrm{d}^2 r' \sum_{i,j=A,B} u_{ij}(r - r') \rho_i(r,t) \rho_j(r',t) + \sum_{i=A,B} \int \mathrm{d}^2 r V_{\text{ext},i}(r,t) \rho_i(r,t)
\]

This quantity is shown in Fig. 8 indicating that only few oscillations are needed to get into the steady behavior. Due to the homogeneous starting configuration the energy oscillation amplitude increases with time. DDFT describes all trends correctly and also provides good data for the potential energies and the associated relaxation time.

The averaged height, as defined by the first moment of the density profile (see Eqn. \([14]\)), can be generalized to a dynamical (time-dependent) quantity \(h_i(t), (i = A, B)\)
FIG. 8: Total potential energy $E_{pot}/(N_A + N_B)$ per particle versus reduced time $t/\tau$, using time period $T_0 = 8\tau$ and swap fraction $\vartheta = 1/4$. The inset shows the short time behavior. The parameters are $M = 0.1, m = 0.24$.

![Graph showing total potential energy](image)

FIG. 9: (Color online) Time-evolution of the mean $A$-particle height $h_A(t)$ versus reduced time $t/\tau$ for different shaking periods $T_0$ and a swap fraction $\vartheta = 1/4$. The parameters are $M = 0.1, m = 0.24$.

![Graph showing mean particle height](image)

The time-dependent heights are another indicative parameter which probes the dynamical response of the whole system. The quantity $h_A(t)$ is shown for two shaking frequencies $\omega = 2\pi/T_0$ in Fig. 9. As a result, the relaxation time is mainly scaling with the Brownian time $\tau$ but is rather insensitive to the periodicity $T_0$. DDFT reproduces the trend with respect to increasing the periodicity $T_0$ but underestimates the actual heights $h_A(t)$, consistent with what we found in the equilibrium case.

\[
    h_i(t) = \frac{\int_{L_0}^{L_y} y \rho_i(y,t) \, dy}{\int_{L_0}^{L_y} \rho_i(y,t) \, dy}, \quad i = A, B. \quad (25)
\]

The mean heights $h_i$ ($i = A, B$) at times $t_n$ are shown in Fig. 11 versus frequency $\omega = 2\pi/T_0$. The dissipative response leads to a decay of the peak as a function of $\omega$. For $\omega \to 0$, we recover a quasi-static equilibrium case while for $\omega \to \infty$, the shaking is so fast that the system does not react at all upon this stimulus. It therefore approaches the limit of an ordinary equilibrium fluid mixture confined between two slits in the absence of gravity where layering is much less pronounced than in the presence of gravity. The crudest model of colloidal shaking is a completely overdamped response to a periodic external stimulus. In this case, the response amplitude scales with the shaking frequency as $1/\omega$. A fit which involves the $1/\omega$ scaling is included in Fig. 11 and provides a good description in the high-frequency regime. The DDFT reproduces these trends and provides good data for $h_B(t_n)$ while underestimating $h_A(t_n)$. Again, we attribute this to the low-density approximation of the functional, where

This is just the time at which the direction of gravity is inverted. Comparing the results to the density profiles predicted by DDFT, the persistence of the boundary layer is indicated by both methods. Fig. 10 depicts density profiles obtained by BD simulations and DDFT for various shaking periods $T_0$. Dynamical density functional data are in qualitative agreement with Brownian dynamics computer simulations results but show the same deficiencies as in the equilibrium case. This indicates that the deviations can be solely attributed to the quality of the density functional but not to the additional adiabatic approximation inherent in any DDFT. Again, as in equilibrium, the amplitude of the outermost density peak is in good agreement, see the inset of Fig. 10.

FIG. 10: (Color online) $A$-particle density profile $\rho_A$ versus reduced height $y/l_A$ upon shaking, obtained by DDFT (curves) and BD simulations (symbols). The inset depicts the outer boundary peak for both methods. Shaking periods $T_0 = 0.8\tau$ and $T_0 = 48\tau$ are shown for a swap fraction $\vartheta = 1/4$. The parameters are $M = 0.1, m = 0.24$.

![Graph showing A-particle density profile](image)

Upon shaking, the boundary layer of the $A$-particles persists. We take a snapshot after the relaxation time at

\[
    t_n = (n - \vartheta)T_0, \quad n = 1, 2, . . . \quad (26)
\]

The parameters are $M = 0.1, m = 0.24$.
the stronger interacting A-particles are treated in a more approximative way than the B-particles.

Within the depletion bubble picture, an effective attraction of a A-particles towards a hard container bottom wall is obtained which leads to boundary layering of the A-particles. We have also studied a periodic inversion of gravity causing perpetuous mutual penetration of the mixture in a slit geometry. This non-equilibrium case of time-dependent gravity is similar to shaking. Upon shaking the boundary layering persists. Our results are based on Brownian dynamics computer simulations and density functional theory. The brazil-nut and boundary layering are very general effects, they do also occur for other long-ranged repulsive interactions and in three spatial dimensions. They are therefore verifiable in future settling experiments on dipolar or charged colloidal mixtures as well as in charged granulates and dusty plasmas.

Future work should address other interparticle interactions. Novel effects are expected for a strongly attractive cross-interactions leading to mutual mixing of A- and B-particles. These interactions are for example realized in oppositely charged suspensions. It would be interesting to check whether a colloidal brazil-nut effect can still be observed in this case. Another option for future study is to superimpose more external fields (e.g., an external electric field) to the gravitational field in order to control the response of the system even more. The latter set-up is relevant for electronic ink.
