ABSTRACT

Context. There is very little information to be found in the literature regarding the detection of planets orbiting chemically peculiar stars.
Aims. Our aim is to determine the detailed chemical composition of the remarkable planet host star KELT-17. This object hosts a hot-Jupiter planet with 1.31 $M_{\text{Jup}}$ detected by transits, and it is one of the more massive and rapidly rotating planet hosts seen to date. We set out to derive a complete chemical pattern for this star, in order to compare it with those of chemically peculiar stars.
Methods. We carried out a detailed abundance determination in the planet host star KELT-17 via spectral synthesis. Stellar parameters were estimated iteratively by fitting Balmer line profiles and imposing the Fe ionization balance using the SYNTHE program together with plane-parallel ATLAS12 model atmospheres. Specific opacities for an arbitrary composition and microturbulence velocity $v_{\text{micro}}$ were calculated through the opacity sampling (OS) method. The abundances were determined iteratively by fitting synthetic spectra to metallic lines of 16 different chemical species using SYNTHE. The complete chemical pattern of KELT-17 was compared to the recently published average pattern of Am stars. We estimated the stellar radius using two methods: a) comparing the synthetic spectral energy distribution with the available photometric data and the Gaia parallax, and b) using a Bayesian estimation of stellar parameters using stellar isochrones.
Results. We found over-abundances of Ti, Cr, Mn, Fe, Ni, Zn, Sr, Y, Zr, and Ba, together with subsolar values of Ca and Sc. Notably, the chemical pattern agrees with those recently published for Am stars, making KELT-17 the first exoplanet host whose complete chemical pattern is unambiguously identified with this class. The stellar radius derived by two different methods agrees to each other and with those previously obtained in the literature.

Key words. stars: abundances – stars: chemically peculiar – planetary systems – stars: individual: KELT-17

1. Introduction

Classical A-type stars have elemental abundances that are close to solar, while Am stars present over-abundances of most heavy elements in their spectra, particularly Fe and Ni, together with under-abundances of Ca and Sc (see e.g. the recent work of Catanzaro et al. 2019, and references therein). Chemically peculiar Am stars rotate more slowly than average A-type stars (e.g., Abt 2000; Niemczura et al. 2015), and most of them belong to binary systems (e.g., North et al. 1998; Carquillat & Prieur et al. 2007; Smalley et al. 2014). These stars may host weak or ultra-weak magnetic fields driven by surface convection (e.g., Folsom et al. 2013; Blazère et al. 2016, 2020). The origin of their peculiar abundances is commonly attributed to diffusion processes due to gravitational settling and radiative levitation (Michaud 1970; Michaud et al. 1976, 1983; Vauclair et al. 1978; Alecian et al. 1996; Richer et al. 2000; Fossati et al. 2007), where the stable atmospheres of slowly-rotating A-type stars would allow the diffusion processes to operate.

The detection of planets orbiting early-type stars in general is more difficult than in late-type stars, due, for example, to the rotational broadening and lower number of spectral lines. Just in the last few years, the detection of planets orbiting A-type stars is slowly growing thanks mainly to detections using transits (e.g., Zhou et al. 2016) and direct imaging (e.g., Nielsen et al. 2019). Recently, Wagner et al. (2016) claimed the detection of a planet by direct imaging orbiting around HD 131399 A, an object classified as a possible Am star (Przybilla et al. 2017). However, this planet detection was then ruled out and attributed to a background star (Nielsen et al. 2017). Subsequent works detected planets around the likely Am star KELT-19 (Siverd et al. 2017) and the mild-Am star WASP-178 (Hellier et al. 2019). Then, the detection of planets orbiting chemically peculiar stars is particularly rare.

Recently, Zhou et al. (2016) announced the detection of a transiting hot-Jupiter planet orbiting the early-type star KELT-17. The authors reported a planet with a mass, radius, and period
of 1.31 $M_{\text{Jup}}$, 1.52 $R_{\text{Jup}}$, and 3.08 days. This host star was only the fourth A-star with a confirmed transiting planet, and it is one of the most massive and rapidly rotating ($\sim44.2$ km s$^{-1}$) planet hosts. The authors adopted a metallicity of $-0.018^{+0.074}_{-0.072}$ for KELT-17 (see their Table 7), that is, a solar or slightly subsolar metallicity, for this notable star.

We currently have an ongoing program aiming to study [Fe/H] in early-type stars with and without planets (Saffe et al., in prep.). The star KELT-17 is included in our sample, and a preliminary inspection of the spectra led us to suspect peculiar abundances. This was surprising, given the previously adopted solar or subsolar [Fe/H] for this star. Then, the exciting possibility of finding a planetary host with an abnormal composition motivated us to perform a detailed chemical analysis on this remarkable star, including different chemical species, to compare it with a more complete chemical pattern. This object would be the second Am star with planets detected to date, and the first one whose individual abundances are derived and compared to an Am pattern in detail.

### 2. Observations

The spectroscopic observations of KELT-17 were acquired at Complejo Astronómico El Leoncito (CASLEO) between April 3 and 4, 2019. We used the Jorge Saúlade 2.15 m telescope equipped with a REOSC echelle spectrograph, selecting, as a cross disperser, a grating with 400 lines mm$^{-1}$. Three spectra of the star were obtained, followed by a ThAr lamp in order to derive an appropriate wavelength versus pixel solution. The data were reduced using IRAF$^2$ standard procedures for echelle spectra. The final spectra covered a visual range of $\lambda\lambda3700–6000$. The resolving power $R$ was $\sim13,000$, and the S/N per pixel measured at $\sim5000$ Å resulted in $\sim350$.

Achieving a proper spectrum normalization is crucial when fitting broad spectral features like H I or strong Ca II lines in A-type stars. In echelle spectra, the normalization of orders is usually a difficult task. To obtain a reliable normalization, we proceeded as follows. First, we fit the continuum of the echelle orders without broad lines using cubic splines (6–9 pieces per order). Then, in problematic echelle orders, we toggled the wavelength-scale to pixels and divided the observed spectrum by the continuum of an adjacent order (or the average of both adjacent orders if available). Finally, we normalized the resulting spectrum by a very low-order polynomial (order 1–3) to compensate for small count level differences between orders.

### 3. Stellar parameters and abundance analysis

The stellar parameters $T_{\text{eff}}$ and $\log g$ were estimated iteratively. We fit the observed H$\beta$ and H$\gamma$ line profiles with synthetic spectra calculated with SYNTHE (Kurucz & Avrett 1981), using ATLAS12 (Kurucz 1993) model atmospheres. Starting opacities were computed for the solar values from Asplund et al. ATLAS12 (Kurucz 1993) model atmospheres. Starting opacities were computed for the solar values from Asplund et al. 2009. We varied temperature and gravity by adopting steps of 100 K and 0.5 dex for $T_{\text{eff}}$ and $\log g$, and then we refined the grid with steps of 1 K in $T_{\text{eff}}$ and 0.01 dex in $\log g$. Synthetic spectra were convolved with a rotational profile (using Kurucz’s command “rotate”) and with an instrumental profile (command 1 On loan from the Institute d’Astrophysique de Liege, Belgium.

### Table 1. Stellar parameters derived in this work for the star KELT-17.

| Parameter | Value       |
|-----------|-------------|
| $T_{\text{eff}}$ (K) | 7471 ± 210 |
| $\log g$ (dex) | 4.20 ± 0.14 |
| $\upsilon_{\text{micro}}$ (km s$^{-1}$) | 2.50 ± 0.50 |
| $\upsilon_{\sin i}$ (km s$^{-1}$) | 43.0 ± 2.4 |

![Fig. 1. Comparison of synthetic (blue dotted line) and observed (black continuous) spectra in the region of the H$\beta$ line for the star KELT-17.](image-url)
Fig. 2. Abundances of different Fe I lines as a function of \(v_{\text{micro}}\), showing different colors for each line. Lower panel: standard deviation of the different lines.

Table 2. Abundances derived in this work for the star KELT-17.

| Specie | Abundance [X/H] | Number of lines | \(\xi\) | \(\Delta\) |
|--------|----------------|----------------|--------|--------|
| Mg I   | \(-0.27 \pm 0.17\) | 3 | 0.10 | 0.13 |
| Mg II  | \(-0.10 \pm 0.35\) | 1 | 0.11 | 0.33 |
| Si II  | \(0.05 \pm 0.44\) | 2 | 0.43 | 0.11 |
| Ca II  | \(-0.99 \pm 0.16\) | 1 | 0.11 | 0.11 |
| Sc II  | \(-0.88 \pm 0.19\) | 2 | 0.07 | 0.17 |
| Ti II  | \(0.21 \pm 0.22\) | 18 | 0.05 | 0.21 |
| Cr II  | \(0.58 \pm 0.13\) | 17 | 0.05 | 0.12 |
| Mn I   | \(0.19 \pm 0.15\) | 6 | 0.09 | 0.12 |
| Fe I   | \(0.46 \pm 0.20\) | 35 | 0.02 | 0.20 |
| Fe II  | \(0.49 \pm 0.15\) | 25 | 0.03 | 0.15 |
| Ni II  | \(0.56 \pm 0.18\) | 1 | 0.11 | 0.14 |
| Zn I   | \(0.39 \pm 0.17\) | 2 | 0.01 | 0.16 |
| Sr II  | \(0.94 \pm 0.27\) | 1 | 0.11 | 0.24 |
| Y II   | \(1.29 \pm 0.42\) | 5 | 0.11 | 0.41 |
| Zr II  | \(0.12 \pm 0.21\) | 1 | 0.11 | 0.18 |
| Ba II  | \(1.47 \pm 0.36\) | 2 | 0.25 | 0.26 |

Notes. The columns show the average abundance and the total error, the number of lines, the error of the average \(\xi\) and the error when varying \(T_{\text{eff}}\), \(\log g\), and \(v_{\text{micro}}\) by their corresponding uncertainties \(\Delta\).

In Fig. 3, we present an example of observed and synthetic spectra of the star KELT-17, for a region between 5190 and 5230 Å. The observed spectrum is shown in black, while synthetic spectra are plotted using red (solar composition) and blue dotted lines (adopted composition). We include the identification of the lines, together with their intensities (between 0 and 1). It is clear from this plot that KELT-17 does not match solar abundances: most metallic lines, such as Fe II and Cr II, are more intense in KELT-17. This is also evident in lines such as Y II 5200.41 Å, which is clearly present in KELT-17 and very weak adopting solar values.

In addition to over-abundances, the chemical pattern of Am stars is also characterized by subsolar values of Ca and Sc (see e.g., Catanzaro et al. 2019). We present in Figs. 4 and 5 the observed and synthetic spectra of KELT-17 near the lines with the number of lines, the error of the average \(\xi\), and the error when varying \(T_{\text{eff}}\), \(\log g\), and \(v_{\text{micro}}\) by their corresponding uncertainties \(\Delta\). With the new abundance values, we derived both new opacities and a model atmosphere and restarted the process again. In this way, abundances are consistently derived using specific opacities calculated for an arbitrary composition using the opacity sampling (OS) method, similar to Saffe et al. (2018).

4. Discussion

In Fig. 3, we present an example of observed and synthetic spectra of the star KELT-17, for a region between 5190 and 5230 Å. The observed spectrum is shown in black, while synthetic spectra are plotted using red (solar composition) and blue dotted lines (adopted composition). We include the identification of the lines, together with their intensities (between 0 and 1). It is clear from this plot that KELT-17 does not match solar abundances: most metallic lines, such as Fe II and Cr II, are more intense in KELT-17. This is also evident in lines such as Y II 5200.41 Å, which is clearly present in KELT-17 and very weak adopting solar values.

In addition to over-abundances, the chemical pattern of Am stars is also characterized by subsolar values of Ca and Sc (see e.g., Catanzaro et al. 2019). We present in Figs. 4 and 5 the observed and synthetic spectra of KELT-17 near the lines.
Fig. 5. Observed and synthetic spectra of KELT-17 in a region near the line Sc II 4246.82 Å. The colors used are the same as in Fig. 3.

Fig. 6. Observed and synthetic spectra of KELT-17 in a region near the line Sc II 5526.82 Å. The colors used are the same as in Fig. 3.

Ca II 3933.68 Å and Sc II 4246.82 Å, using the same notation. Notably, the Ca II line in KELT-17 (black line) is much weaker than in a solar composition spectrum (red line). Similarly, in Fig. 5 we can see that the lines of Fe II and Cr II are more intense in KELT-17, while the line Sc II 4246.82 Å is weaker than a supposed solar-like composition. A clearer example of the weakness of Sc II in the star KELT-17 can be seen in Fig. 6. In this case, we plotted a region near the line Sc II 5526.82 Å. A solar-like composition should clearly present this line (red line), while in the spectrum of KELT-17, this line is almost absent (black line).

Over-abundances and subsolar values of species shown in Figs. 3–6 are similar to those of Am stars. A more quantitative comparison can be performed by directly comparing the abundance pattern of KELT-17 with those of Am stars in general. In Fig. 7, we show the chemical pattern as the abundance versus atomic number for the different chemical species. For the abundance pattern of Am stars (blue in Fig. 7), we used the average values recently derived by Catanzaro et al. (2019) from a sample of 62 Am stars, where vertical bars correspond to their maximum and minimum values. The abundance values derived for the star KELT-17 are shown in black. These values correspond to 16 different species identified in the spectrum: Mg I, Mg II, Si II, Ca II, Sc II, Ti II, Cr II, Mn I, Fe I, Fe II, Ni I, Zn I, Sr II, Y II, Zr II and Ba II. From this plot, we see that KELT-17 agrees in general with the chemical characteristics of Am stars.

In Fig. 8, we present the spectral energy distribution computed with ATLAS12 model atmospheres and the available photometry in different bands, adopting a Gaia parallax of $4.387 \pm 0.048$ mas (Gaia Collaboration 2018). We used the $B_T$ and $V_T$ Tycho-2 magnitudes (Hog et al. 2000), $G$, $G_{BP}$ and $G_{RP}$ Gaia DR2 magnitudes (Gaia Collaboration 2018), The Amateur Sky Survey V band (TASS, Droege et al. 2006), the Carlsberg Meridian Telescope survey r’ band (Evans et al. 2002), 2MASS J, H and Ks bands (Cutri et al. 2003), and WISE magnitudes (Cutri et al. 2012). The reddening was calculated according to the distance and position using the extinction maps of Schlegel et al. (1998), following the procedure of Bilir et al. (2008). From this plot, we estimated a stellar radius of $1.697 \pm 0.063 R_\odot$. We also

https://irsa.ipac.caltech.edu/applications/DUST/
derived the radius through a Bayesian analysis using the PARSEC stellar isochrones (Bressan et al. 2012), from the $T_{\text{eff}}$, an apparent magnitude of $V = 9.23 \pm 0.02$ from the Tycho-2 catalog (Hog et al. 2000), and the Gaia parallax. In this way, we obtained $R = 1.680 \pm 0.092 \, R_{\odot}$ for the star KELT-17. We adopted a global solar composition when using isochrones with this chemically peculiar star, similar to previous works (e.g., Pöhl et al. 1998; Kochukhov & Bagnulo 2006). Both estimations of the stellar radius agree with the previous determination of Zhou et al. (2016), who derived $R = 1.645^{+0.086}_{-0.055} \, R_{\odot}$. Then, the planetary radius previously estimated using the transit depth does not change significantly.

5. Summary

We performed a chemical analysis of the exoplanet host star KELT-17 and found over-abundances of Ti, Cr, Mn, Fe, Ni, Zn, Sr, Y, Zr, and Ba, together with subsolar values of Ca and Sc. The chemical pattern agrees with those recently published concerning Am stars, with KELT-17 being the first exoplanet host whose complete chemical pattern is unambiguously identified with this class. We also derived the stellar radius using two different methods: obtaining good agreement between them and with those previously derived in the literature. Therefore, the classification of KELT-17 as an Am star has no significant impact on the corresponding planet parameters.
