I. INTRODUCTION

Since the discovery of the $J/\psi$ and $\Upsilon$ mesons [1,2] the study of heavy quark-antiquark systems has provided valuable input for our understanding of quantum chromodynamics (QCD). However, despite being one of the simplest systems in QCD it has proven difficult historically to describe the production properties of these states adequately. Results on $J/\psi$ and $\Upsilon$ hadroproduction and polarization [3–12] exhibit inconsistencies between measurements and theoretical predictions [13].

Measurements at the Large Hadron Collider (LHC) of differential production spectra of various charmonium and bottomonium states together with measurement of their spin alignments, prompt double-quarkonia production, and production of quarkonia in association with photons, vector bosons, or open heavy-flavor final states will allow discrimination between different theoretical approaches based on color-singlet corrections [14–16], color-octet terms [17], the $k_t$-factorization approach [18], and other production models [19], and provide additional input toward an improved understanding of quarkonium hadroproduction.

Studies of bottomonium production complement concurrent studies of charmonium systems due to the larger mass of the bottom quark compared to the charm quark, allowing more dependable theoretical calculations than in the charmonium family, which suffer from poor perturbative convergence [17]. Extension of cross section measurements to higher meson transverse momenta provides valuable input to improvements in the theoretical description since in this regime different processes can dominate and, experimentally, the impact of spin-alignment uncertainties are mitigated.

Taking advantage of the large increase in integrated luminosity delivered by the LHC in 2011, this paper updates a previous measurement [8] and reports the $\Upsilon(1S)$ cross section presented differentially in two intervals of absolute $\Upsilon$ rapidity [20], $|y|$, and 50 intervals of $\Upsilon$ transverse momentum $p_T$ and rapidity are presented. These cross sections are obtained assuming unpolarized production. If the production polarization is fully transverse or longitudinal with no azimuthal dependence in the helicity frame, the cross section may vary by approximately ±20%. If a nontrivial azimuthal dependence is considered, integrated cross sections may be significantly enhanced by a factor of 2 or more. We compare our results to several theoretical models of $\Upsilon$ meson production, finding that none provide an accurate description of our data over the full range of $\Upsilon$ transverse momenta accessible with this data set.
to $Y$ production [15,16] such as from associated $Y + b\bar{b}$
production may play a more important role, and the impact of
the dependence of the production cross section on the spin
alignment of the $Y$ is relatively small. Both the fiducial cross
section, measured in the kinematic region with muon trans-
verse momentum $p^\mu_T > 4$ GeV and muon pseudorapidity
$|\eta^\mu| < 2.3$, and the corrected cross section, which is defined
in this paper as the cross section in the $p_T^\mu-\eta$ phase space of
the $Y$ corrected for the acceptance of the decay products to
the full $Y$ production phase space, are reported. In the former
case, the results have no dependence on assumptions about $Y$
spin alignment, while the latter measurements are more easily
compared to model predictions and to the results of
other experiments.

II. THE ATLAS DETECTOR

The ATLAS detector [22] is composed of an inner
tracking system, calorimeters, and a muon spectrometer.
The inner detector directly surrounds the interaction point
and consists of a silicon pixel detector, a silicon microstrip
detector, and a transition radiation tracker, all immersed in
a 2 T axial magnetic field. It covers the pseudorapidity [20]
range $|\eta| < 2.5$ and is enclosed by a calorimeter system
containing electromagnetic and hadronic sections.
Surrounding the calorimeters is the large muon spectrom-
ter built with three air-core toroids. This spectrometer is
equipped with precision detectors (monitored drift tubes
and cathode strip chambers) that provide precise measure-
ments in the bending plane within the pseudorapidity range
$|\eta| < 2.7$. In addition, resistive plate and thin gap cham-
bers with fast response times are used primarily to con-
struct muon triggers in the ranges $|\eta| < 1.05$ and
$1.05 < |\eta| < 2.4$ respectively but are also used to provide
position measurements in the nonbending plane and to
improve pattern recognition and track reconstruction.
Momentum measurements in the muon spectrometer are
based on track segments formed in at least two of the three
precision chamber planes.

The ATLAS detector employs a three-level trigger sys-
tem [23], which reduces the 20 MHz proton bunch collision
rate to the several hundred Hz transfer rate to mass storage.
The level-1 muon trigger searches for hit coincidences
between different muon trigger detector layers inside pre-
programmed geometrical windows that bound the path of
triggered muons of given transverse momentum and pro-
vide a rough estimate of its position within the pseudorap-
idity range $|\eta| < 2.4$. At level-1, muon candidates are
reported in “regions of interest” (RoIs). Only a single
muon can be associated with a given RoI of spatial extent
$\Delta\phi \times \Delta\eta = 0.1 \times 0.1$. This limitation has a small effect
on the trigger efficiency for $Y$ mesons, corrected for in the
analysis using a data-driven method based on analysis of
$J/\psi \rightarrow \mu^+\mu^-$ and $Y \rightarrow \mu^+\mu^-$ decays. The level-1 trig-
ger is followed in sequence by two subsequent higher-level,
software-based trigger selection stages. Muon candidates
reconstructed at these higher levels incorporate, with in-
creasing precision, information from both the muon spec-
trometer and the inner detector and reach position and
momentum resolution close to that provided by the offline
muon reconstruction.

III. DATA SET AND EVENT SELECTION

Data for this study were collected during the 2011 LHC
proton-proton running period between March and August
using a trigger that requires the presence of two muon
candidates with opposite charges that are subject to a fit
constraining them to a common vertex while taking into
account track parameter uncertainties. A very loose selec-
tion on vertex $\chi^2$, which is fully efficient for signal candi-
dates, was imposed to ensure proper fit convergence, as
well as the requirement of opposite charge and that $p^\mu_T >$
4 GeV and $|\eta^\mu| < 2.3$. This trigger was largely unpres-
called and collected data at a rate of approximately 20 Hz in
this period of data taking.

Events are required to contain at least one primary vertex
candidate that has at least five tracks with $p_T >$
0.4 GeV, and at least two muons identified by associating
candidates found in the muon spectrometer with tracks
reconstructed in the inner detector [8,22]. Multiple scatter-
ing in the calorimeters and toroids of the ATLAS detector
degrades the muon spectrometer resolution for low energy
particles. As the majority of muons selected for this analy-
sis have low momentum, we assign values for parameters
such as $p_T$ and $\eta$ to the muons based on track fits using
inner detector information only. To ensure accurate inner
detector measurements, each muon track must contain at
least six silicon microstrip detector hits and at least one
pixel detector hit. Muon candidates passing these criteria
are required to have $p^\mu_T > 4$ GeV and $|\eta^\mu| < 2.3$ and a
successful fit to a common vertex.

Good spatial matching ($\Delta R = \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2}$ < 0.01)
between the muon candidate in both the offline reconstruc-
tion and the trigger used to select the event is required to
facilitate data-driven estimates of the dimuon trigger effi-
ciency. Furthermore, both muons forming an $Y$ candidate
must be associated to their trigger-level candidates in this
manner. In this way, the efficiency of the trigger require-
ments on the dimuon candidate are incorporated into the
trigger efficiency correction. All dimuon candidates pass-
ing these criteria are retained for analysis.

The distribution of the invariant mass of the $\mu^+\mu^-$
system is shown in Fig. 1 for the selected dimuon candi-
dates. As is apparent from the plot, the mass resolution
(120 MeV) for dimuon candidates detected in the central
region of the detector ($|y^{\mu\mu}| < 1.2$) is significantly bet-
ter than the resolution (214 MeV) for those candidates falling
into the forward region ($1.2 \leq |y^{\mu\mu}| < 2.25$). A total of
$3.9 \times 10^6$ and $2.3 \times 10^6$ candidates with $8 < m_{\mu\mu} <$
11.5 GeV are reconstructed in the central and forward
regions, respectively.
IV. CROSS SECTION DETERMINATION

Differential Y cross sections are measured according to the relation

\[
\frac{d^2\sigma}{dp_T dy} \times \text{Br}(Y \rightarrow \mu^+ \mu^-) = \frac{N_Y}{\int \mathcal{L} dt \times \Delta p_T \times \Delta|y|} \tag{1}
\]

where \(\text{Br}(Y \rightarrow \mu^+ \mu^-)\) represents the appropriate branching fraction of the Y \((nS)\) to dimuons, \(\int \mathcal{L} dt\) is the integrated luminosity, \(\Delta p_T\) and \(\Delta|y|\) are the bin sizes in Y transverse momentum and rapidity, respectively, and \(N_Y\) is the corrected number of observed Y(1S), Y(2S), or Y(3S) mesons in a bin. Corrections are applied to account for selection efficiencies, bin migration effects due to finite detector resolution, and, in the case of corrected cross section measurements, acceptance.

Determination of the cross sections proceeds through several steps. First, a weight is determined for each selected dimuon candidate equal to the inverse of the total efficiency for the candidate. Second, a fit is performed to the distribution of weighted events binned in dimuon invariant mass, \(m_{\mu\mu}\), to determine the number of Y \((nS)\) mesons (with \(n = 1, 2, 3\)) produced in each \((p_T^\mu, \eta^\mu)\) bin. Third, these values are corrected for \((p_T^\mu, \eta^\mu)\) bin migrations. Finally, the differential cross section multiplied by the \(Y \rightarrow \mu^+ \mu^-\) branching fraction is calculated for each state using the integrated luminosity and the \(p_T\) and \(y\) bin widths as in Eq. (1).

The weight, \(w\), for each Y candidate includes the fraction of produced \(Y \rightarrow \mu^+ \mu^-\) decays with both muons falling into the kinematic region \(p_T^\mu > 4\) GeV and \(|\eta^\mu| < 2.3\) (the acceptance, \(\mathcal{A}\), is used only in calculating corrected cross sections), the probability that a candidate falling within the acceptance passes the offline reconstruction requirements (the reconstruction efficiency, \(\epsilon_{\text{reco}}\)), and the probability that a reconstructed event passes the trigger selection (the trigger efficiency, \(\epsilon_{\text{trig}}\)). The weights assigned to a given candidate when calculating the fiducial (\(w_{\text{fid}}\)) and corrected (\(w_{\text{tot}}\)) cross sections are then given by

\[
w_{\text{fid}} = (\epsilon_{\text{reco}} \cdot \epsilon_{\text{trig}})^{-1}, \quad w_{\text{tot}} = (\mathcal{A} \cdot \epsilon_{\text{reco}} \cdot \epsilon_{\text{trig}})^{-1}. \tag{2}
\]

A. Acceptance

The kinematic acceptance \(\mathcal{A}(p_T, y)\) is the probability that the muons from an Y with transverse momentum \(p_T\) and rapidity \(y\) fall into the fiducial volume of the detector defined by the \(p_T^\mu > 4\) GeV and \(|\eta^\mu| < 2.3\) selection applied to each muon in the dimuon pair. In order to calculate the acceptance as a function of the rapidity and transverse momentum of each of the Y states, taking into account possible angular dependences in their decays, we use an analytic formula describing the decay of Y states in their decay frame [24],

\[
\frac{d^2N}{d\cos\theta^* d\phi^*} \propto 1 + \lambda_\phi \cos 2\theta^* + \lambda_\phi \sin^2\theta^* \cos 2\phi^* + \lambda_\phi \sin 2\theta^* \cos \phi^*. \tag{3}
\]

The helicity frame is used, where \(\theta^*\) is the polar angle between the \(\mu^+\) momentum in the Y decay frame and the direction of the Y momentum in the laboratory frame. The corresponding azimuthal angle \(\phi^*\) is the angle between the quarkonium production plane (defined in the quarkonium decay frame by the two momenta of the incoming protons in that frame) and the quarkonium decay plane in the lab frame.
The \( \lambda_i \) coefficients parametrize the spin-alignment state of the \( Y \). In some parts of the phase space the acceptance may depend on these parameters quite strongly. We have identified five extreme cases that lead to the largest possible variations of acceptance within the phase space of this measurement and define an envelope in which the results may vary under any physically allowed spin-alignment assumption: isotropic distribution independent of \( \theta^* \) and \( \phi^* \) \((\lambda_\theta = \lambda_\phi = \lambda_{\theta\phi} = 0)\), labeled FLAT; longitudinal alignment \((\lambda_\theta = -1, \lambda_\phi = \lambda_{\theta\phi} = 0)\), labeled LONG; and three types of transverse alignment \((\lambda_\theta = +1, \lambda_\phi = \lambda_{\theta\phi} = 0)\), labeled \( T + 0 \); \((\lambda_\theta = +1, \lambda_\phi = +1, \lambda_{\theta\phi} = 0)\), labeled \( T + + \); \((\lambda_\theta = +1, \lambda_\phi = -1, \lambda_{\theta\phi} = 0)\), labeled \( T - + \). The central values of our measurements are derived under the isotropic production assumption. The spread in corrected cross section results derived under all five assumptions is used to quantify the full envelope of possible variations of the result due to spin alignment. Some constraints on physically allowed \( \lambda_i \) combinations exist [24,25]. In particular, \( \lambda_{\theta\phi} \) must be zero for \( \lambda_\theta = \pm 1 \) and any \( \lambda_\phi \), and \(|\lambda_{\theta\phi}| \leq 0.5 \) for \( \lambda_\theta = \lambda_\phi = 0 \). Acceptance corrections with nonzero \( \lambda_{\theta\phi} \) were found to lead to corrections with smaller or equal variations from the isotropic scenario than any parameter-space scenarios on the \( \lambda_\theta - \lambda_\phi \) plane. Acceptance weights for each polarization scenario, including those with nonzero \( \lambda_{\theta\phi} \), can be found in HEPDATA [26].

Figure 2 presents the two-dimensional acceptance map for \( Y(1S) \), as a function of the \( Y \) transverse momentum and absolute rapidity in the unpolarized (FLAT) acceptance scenario as well as the maximum relative variation (ratio of largest to smallest acceptance correction) of the acceptance maps across all spin-alignment scenarios.

Acceptance is significantly decreased at very high rapidities due to the muon pseudorapidity requirement of \(|\eta^\mu| < 2.3\). When \( Y \) events are produced at rest, both muons are likely to be reconstructed in the muon spectrometer on opposite sides of the detector. When the \( Y \) has a sufficient boost, the two muons are more likely to be found in the same side of the detector and the probability that at least one muon is below the required \( p_T^\mu \) threshold increases, leading to a drop in acceptance. At higher \( p_T \) the \( Y \) imparts greater momentum to the two muons, the likelihood of a muon being below threshold decreases, and the acceptance asymptotically approaches 100%. As \( Y \) transverse momentum increases the variation of the acceptance corrections between spin-alignment scenarios decreases, becoming \( \leq 10\% \) at the largest \( p_T \) ranges studied. Similar behaviors are observed in the acceptance maps for the \( Y(2S) \) and \( Y(3S) \).

This spin-alignment systematic uncertainty only applies to the corrected cross section measurements. For fiducial cross sections, measured in the kinematic region \( p_T^\mu > 4\text{ GeV} \) and \(|\eta^\mu| < 2.3\), we do not have to correct our results to the full phase space of produced \( Y \) mesons. Spin alignment can thus affect only our estimates of the reconstruction and trigger efficiencies. Since we measure these in many bins of muon \( p_T \) and \( \eta \), effects from differing distributions of events over individual bins due to different spin-alignment assumptions are negligible compared to other sources of systematic uncertainty.

### B. Reconstruction and trigger efficiencies

The efficiency of the offline reconstruction criteria for events with muons within the fiducial region is given by

\[
\epsilon_{\text{reco}} = \epsilon_{\text{trk}}(p_T^{\mu_1}, \eta_1) \times \epsilon_{\text{trk}}(p_T^{\mu_2}, \eta_2) \epsilon_{\mu}(p_T^{\mu_1}, q_1 \cdot \eta_1^{\mu_1}) \times \epsilon_{\mu}(p_T^{\mu_2}, q_2 \cdot \eta_2^{\mu_2}).
\]

In this equation, \( q \) represents the charge of the muon and the identities of the two muons are labeled with indices 1, 2. The efficiency of the track selection criteria, \( \epsilon_{\text{trk}} \), for
tracks originating from real muons is determined in Ref. [7] using data collected in 2010. Because of the presence of additional pp interactions in the same and neighboring bunch crossings in 2011 data the systematic uncertainty on the tracking efficiency has increased, with $\varepsilon_{\text{track}}$ assessed to be $99 \pm 1.0\%$ over the whole kinematic range.

The efficiency to reconstruct a muon, $\varepsilon_\mu$, is derived using a tag-and-probe method on $J/\psi \rightarrow \mu^+\mu^-$ data. The tag muon corresponds to a muon candidate with $p_T^\mu > 4$ GeV and $|\eta^\mu| < 2.4$ and must have fired a single-muon trigger in the event, as required by the trigger matching algorithms. The probe track is only required to pass the inner detector track quality, $p_T$, and $\eta$ cuts and be consistent with having the same vertex as the identified tag muon. This technique provides a sample of muon candidates unbiased with respect to both trigger and offline reconstruction, and with favorable signal to background ratio.

The muon reconstruction efficiency is then derived in two-dimensional $p_T$-\eta bins [14 muon $p_T$ intervals and 26 charge-signed muon pseudorapidity ($q \cdot \eta$) intervals]. The ratio of the fitted $J/\psi \rightarrow \mu^+\mu^-$ signal yield for those probe tracks identified as muons to the fitted signal yield for all probe tracks in these double-differential intervals is identified as the single-muon reconstruction efficiency.

Because of the toroidal magnetic field, muons with positive (negative) charge are bent towards larger (smaller) pseudorapidity. This introduces a charge dependence in the muon reconstruction efficiency. We calculate efficiencies as a function of charge-signed pseudorapidity as negative muons at positive rapidities are affected in the same manner as positive muons in negative rapidities. The charge dependence is particularly noticeable at very large $|\eta|$ where the muon can be bent outside of the geometrical acceptance of the detector. In particular, at low $p_T$, where the muons of particular charge may be bent away from (rather than toward for the opposing charge) the middle/outer spectrometer planes, they will not be identified as muons.

The efficiency of the dimuon trigger to select events that have passed the offline selection criteria, $\varepsilon_{\text{trig}}$, is also calculated from data. This can be factorized into three terms:

$$\varepsilon_{\text{trig}} = \varepsilon_{\text{RoI}}(p_T^{\mu_1}, q_1 \cdot \eta_1^\mu) \varepsilon_{\text{RoI}}(p_T^{\mu_2}, q_2 \cdot \eta_2^\mu) c_{\mu_\mu}(\Delta R, |y^{\mu\mu}|),$$

where $\varepsilon_{\text{RoI}}$ is the efficiency of the trigger system to find an RoI for a single muon with transverse momentum, $p_T^\mu$, and charge-signed pseudorapidity, $q \cdot |\eta^\mu|$, and $c_{\mu_\mu}$ is a correction for effects related to the dimuon elements of the trigger. This correction accounts for the dimuon vertex and opposite charge requirements, and for loss of efficiency in the dimuon trigger if the two muons are close enough together to register only as a single RoI.

The dimuon correction, $c_{\mu_\mu}$, itself consists of two components

$$c_{\mu_\mu}(\Delta R, y^{\mu\mu}) = c_q(y^{\mu\mu}) \times c_{\Delta R}(\Delta R, y^{\mu\mu}),$$

each evaluated in three separate regions of dimuon rapidity: barrel ($|y^{\mu\mu}| \leq 1.0$), barrel-endcap transition ($1.0 < |y^{\mu\mu}| \leq 1.2$), and endcap ($1.2 \leq |y^{\mu\mu}| < 2.25$), to account for the different behaviors of these corrections in these regions. The correction $c_q$ is due to the effect of vertex and opposite charge requirements on the trigger and is determined from the efficiency at large dimuon angular separations. No difference was observed from deriving the result as a function of $\Delta \eta$ and $\Delta \phi$ separately rather than versus $\Delta R$. The asymptotic values are found using the ratio of candidate $J/\psi \rightarrow \mu^+\mu^-$ decays selected by the standard dimuon trigger to those selected by a similar dimuon trigger that makes no charge or vertex requirements. These values are found to be $99.1 \pm 0.4\%$, $97.5 \pm 0.9\%$, $95.2 \pm 0.4\%$ in the barrel, transition, and endcap regions, respectively.

We extract this dependence on $\Delta R$ in the same three regions of dimuon rapidity as used for $c_q$ from a sample of offline reconstructed $J/\psi \rightarrow \mu^+\mu^-$ and $Y \rightarrow \mu^+\mu^-$ candidates with $p_T^{\mu} > 8$ GeV selected using a single-muon trigger with a threshold of 18 GeV. The 8 GeV requirement on the lower $p_T$ muon is made to ensure that the efficiency for the trigger system to identify RoIs compatible with muons of $p_T > 4$ GeV reached its plateau value. The $\Delta R$ dependence of $c_{\Delta R}$ is then extracted from the fraction of fitted dimuon candidates in a $\Delta R$ interval within this control sample selected using auxiliary triggers that additionally pass the dimuon trigger used in this analysis.

The final component of the dimuon trigger efficiency, $\varepsilon_{\text{RoI}}$, represents the single-muon trigger efficiency with a threshold of $p_T^\mu > 4$ GeV. This is measured using well-reconstructed $J/\psi \rightarrow \mu_1\mu_2$ candidates in data that pass a single-muon trigger (with a threshold of 18 GeV). The ratio of the yield of $J/\psi$ candidates (determined by fitting the invariant mass distributions) that pass both this single-muon trigger and the 4 GeV $p_T^\mu$ threshold dimuon trigger used in this analysis, to the yield of $J/\psi$ candidates that pass the single-muon trigger is identified as the single-muon trigger efficiency $\varepsilon_{\text{RoI}}$ in the $p_T^\mu$ and $q \cdot |\eta^\mu|$ interval considered. In each case, the reconstructed muon(s) are matched to the muon(s) that triggered the event for each of the single or dimuon triggers. The number of candidates passing the dimuon trigger is then further corrected by $c_{\mu_\mu}$ for dimuon correlation effects [27].

The individual and overall efficiencies and weight corrections, calculated using the methods described above, are shown as functions of $p_T^\mu$ and $|y^{\mu\mu}|$ in Fig. 3 for the $Y(1S)$. 

052004-5
C. Extracting the number of $Y$ mesons

The number of produced $Y(nS)$ mesons used in our cross section determination is found by fitting signal and background functions to the $m_{\mu\mu}$ spectrum of weighted $Y$ candidates. The use of per-candidate weights rather than average weights allows us to correct for acceptance and efficiency without introduction of biases associated with the use of average values for these quantities. We determine the $Y$ differential cross sections separately for each spin-alignment scenario. We perform least squares fits to $m_{\mu\mu}$ histograms filled using the weights, $w$, for each candidate in bins of dimuon transverse momentum, $p_T^{\mu\mu}$, and rapidity, $y$. The form of the $\chi^2$ for each ($p_T^{\mu\mu}$, $|y|$) bin is

$$\chi^2 = \sum_{i=m_{\mu\mu}}^{n_{\text{data}}} \frac{(n_{\text{data}} - n_{\text{pred}}^i)^2}{\sigma_i^2}, \quad n_{\text{data}} = \sum_{j=N_i} w_j; \quad \sigma_i^2 = \sum_{j=N_i} w_j^2,$$

(7)

where $N_i$ represents the number of $Y(nS)$ candidates in bin $i$.

Predictions for each bin are constructed using four sources of dimuon candidates:

$$n_{\text{pred}}(m_{\mu\mu}) = N_{1S}F_{1S}(m_{\mu\mu}; f_{1S}) + N_{2S}F_{2S}(m_{\mu\mu}; f_{2S}) + N_{3S}F_{3S}(m_{\mu\mu}; f_{3S}) + F_{\text{bkgd}}(m_{\mu\mu}; f_{\text{bkgd}}),$$

(8)

where the $f_X$ here represent fit function parameters and the $F_X$ are normalized probability density functions. In order to avoid bias due to the choice of fit model, several parametrizations of signal and background, which describe the data well, are used.

Each of the three $Y$ resonances are parametrized by single Gaussian, double Gaussian, or crystal ball functions, chosen to provide a reasonable description of the experimental mass resolution and energy loss effects that dominate the observed signal line shapes. The background parametrizations vary with dimuon $p_T$. At low $p_T^{\mu\mu}$, and for all rapidity bins, an error function multiplied by either a second-order polynomial, or a second-order polynomial plus an exponential, is used to model $m_{\mu\mu}$ turn-on effects accurately. At mid $p_T^{\mu\mu}$ a second-order polynomial, or second-order polynomial plus an exponential is adequate to describe the shape of the background under the $Y$ peaks. At high $p_T^{\mu\mu}$ a first-order polynomial or a first-order polynomial plus an exponential is sufficient to describe the background contribution. Average fitted values for the numbers of $Y(nS)$ mesons ($N_{1S}, N_{2S}, N_{3S}$) taken over all combinations of signal and background models are used in the extraction of cross sections, while the maximum deviation of any fit result from the average is used as an estimate of the fit model systematic uncertainty.

In the fits $N_{1S}, N_{2S}, N_{3S}$, the peak mass of the $Y(1S)$ meson ($M_{1S}$), parameters describing the shape of the

FIG. 3 (color online). Efficiency and acceptance corrections contributing to the overall fiducial and corrected efficiencies (and the inverse of the efficiency, the weight) as a function of the $Y(1S)$ $p_T^{\mu\mu}$ in the central (top) and forward (middle) regions of the detector and as a function of $|y|$ (bottom).
$Y \to \mu^+\mu^-$ mass distribution, and the background parameters are allowed to vary freely while $M_{2S}, M_{3S}$ are fixed relative to $M_{1S}$ using measured mass splittings [28]; and the line-shape width parameters $\sigma_{2S}, \sigma_{3S}$ are related linearly in $m_{\mu\mu}$ to $\sigma_{1S}$. The distribution of the $\chi^2$ probabilities from the fits are uniformly distributed indicating that our signal and background parametrizations provide good descriptions of the data. Figure 4 shows the invariant

![Graphs showing fits to the efficiency-corrected $m_{\mu\mu}$ spectra for candidates in the low (0.5–1.0 GeV; top), mid (20–21 GeV; middle), and high (40–45 GeV; bottom) $p_T$ intervals, for central (left) and forward (right) dimuon rapidities. Fit results are shown for the simplest fit model considered: a single Gaussian signal plus either a second-order polynomial multiplied by an error function (low $p_T$), second-order polynomial (mid $p_T$), or first-order polynomial (high $p_T$) background parametrization.]}
mass distribution of the fitted signal region for representa-
tive low, mid, and high $Y_{p_T}$ intervals, in both the central
and forward rapidity regions.

In order to account for bin migrations due to finite
detector resolution, corrections in $p_T^{\mu\mu}$ are derived by first
fitting a smooth analytic function to the background-
subtracted $p_T^{\mu\mu}$ spectra of $Y$ events in data. This fitted
distribution is deconvolved with a Gaussian distribution
using a Gauss-Hermite quadrature integration technique,
with a $p_T$ resolution derived from the fitted invariant
mass and muon angular resolutions in data. From the
distributions with and without convolution, migration
corrections bin-by-bin are derived. These corrections are
found to be within 0.5% of unity for central rapidities and
within 1% of unity for forward rapidities. The number of
efficiency-corrected $Y \rightarrow \mu^+ \mu^-$ decays extracted from
the fits in each $(p_T^{\mu\mu}, y^{\mu\mu})$ bin are corrected for the
difference between true and reconstructed values of the
dimuon $p_T$ and rapidity. Using a similar technique, bin
migration corrections as functions of $y^{\mu\mu}$ are found to be
negligible.

V. SYSTEMATIC UNCERTAINTIES

We consider the following sources of systematic uncer-
tainty on the $Y(nS)$ differential cross sections: luminosity
determination, reconstruction and trigger efficiencies, mi-
gration between $p_T^{\mu\mu}$ and $|y^{\mu\mu}|$ bins due to resolution,
acceptance corrections, and the background and signal fit
models used. The range of these uncertainties for the three
$Y$ states is summarized in Table I and their breakdown in
each source is given for the corrected cross section analysis
in Figs. 5–7.

The relative luminosity uncertainty of 3.9% is described
in more detail in Ref. [29]. Other sources of systematic
uncertainty are discussed below. As the statistical compo-
nents of the uncertainties associated with the determination
of $e_{\text{reco}}$ and $e_{\text{sig}}$ are dominant, the uncertainties on the cross
sections are derived from the statistics of the control samples
used to extract them using a series of pseudoexperiments,
randomly varying the weights used for each $Y$ candidate in
data, according to the uncertainties on the efficiency maps.
Systematic uncertainties associated with the fit model used
to extract the number of $Y(nS)$ decays from our dimuon data
sample are quantified by taking the largest deviation of the
fitted values of $N_{nS}$ found in the six possible model combi-
nations from the average value. Systematic effects, due to
differences in the underlying kinematic distributions of the
control sample and the data distributions, are found to be
negligible due to the fine differential binning of the
efficiency and acceptance corrections.

Uncertainties associated with the acceptance correction
include statistical uncertainties on the determination of the
correction in fine $p_T$ and rapidity bins. This constitutes
approximately a 0.5% uncertainty across the measured
spectrum. A shift in the interaction point along the beam-
line axis, $z$, influences the acceptance particularly at large
rapidity. To estimate the impact of this effect, the accept-
cences were recalculated with shifts in $z$ by ±62 mm,
corresponding to one Gaussian standard deviation of the
vertex $z$ position distribution in the analyzed data, and the
variation in the measured cross sections was calculated as a
function of $Y_{p_T}$ and rapidity. These variations result in
uncertainties on the acceptance corrections of 0.4%–0.7%
as a function of $p_T$, and 0.6%–1.5% as a function of
rapidity, growing toward larger rapidities and lower transverse
momenta. We estimate the correction to the number of $Y \rightarrow \mu^+ \mu^-$
decays fitted in each $(p_T^{\mu\mu}, y^{\mu\mu})$ bin for differences between reconstructed and true values of
$p_T^{\mu\mu}$ due to bin migration depends on a knowledge of the
dimuon $p_T$ resolution. Allowing this resolution to vary
within its uncertainty results in a negligible change in the
$Y(nS)$ cross sections.

As mentioned earlier, $Y$ spin-alignment effects have an
impact on the determination of cross sections extrapolated
to full phase space. As in the ATLAS measurement of $J/\psi$
production [7], we quote an uncertainty due to $Y$ spin

| Source                        | Relative uncertainty $[Y(1S)/Y(2S)/Y(3S)]$ [%] |
|-------------------------------|-----------------------------------------------|
|                              | $|y^{\mu\mu}| < 1.2$                      | $1.2 \leq |y^{\mu\mu}| < 2.25$ |
| Statistical uncertainty       | $1.5$–$10/2$–$10/3$–$3$                   | $2$–$15/2.5$–$12/4$–$18$ |
| Fit model                     | $0.3$–$2/0.3$–$10/0.3$–$15$               | $0.4$–$10/0.3$–$5.0$–$0.2$–$12$ |
| Luminosity                    | $3.9$                                        | $3.9$ |
| Trigger efficiency            | $2.0$–$3.0/1.0$–$2.0/1.0$–$2.0$           | $2.0$–$3.0/2.0$–$4.0/2.0$–$7.0$ |
| Muon reconstruction efficiency| $0.7$–$2.0/0.4$–$1.2/0.4$–$1.2$           | $0.5$–$5.0/0.4$–$3.0/0.4$–$3.0$ |
| Acceptance corrections        | $0.7$–$1.5$                                 | $0.7$–$1.5$ |
| Track reconstruction efficiency| $1.0$                                       | $1.0$ |
alignment by comparing results obtained using the unpolarized assumption ($\lambda_{\phi} = \lambda_{d} = \lambda_{d\phi} = 0$) to those derived under the other four extreme parameter combinations. The size of the possible variation in each bin is taken to be the largest positive and negative deviation from the unpolarized baseline result. We provide the cross section results for each of the spin-alignment scenarios along with tabulated values [26] of the weight corrections so that the corrected data can be determined in terms of any spin-alignment scenario.

VI. RESULTS AND DISCUSSION

We measure the differential cross section multiplied by the dimuon branching fractions of $\Upsilon(1S)$, $\Upsilon(2S)$, and $\Upsilon(3S)$ mesons as a function of $Y$ transverse momentum and rapidity, both in a fiducial region defined by $p_T > 4$ GeV, $|\eta^\mu| < 2.3$ (free from spin-alignment uncertainties) and corrected back to the full muon decay phase space with $|y^\mu| < 2.25$. We additionally present measurements of the production cross sections of the $\Upsilon(2S)$ and $\Upsilon(3S)$ relative to the $\Upsilon(1S)$ as a function of $\Upsilon(1S)$ transverse momentum and rapidity. Tabulated results of all measurements presented in this paper are available in HEPDATA [26].

A. Fiducial cross sections

Differential cross sections multiplied by the $Y \rightarrow \mu^+ \mu^-$ branching fractions, $d^2\sigma/dp_Tdy \times Br(Y \rightarrow \mu^+ \mu^-)$, are calculated within the fiducial acceptance of our analysis ($p_T > 4$ GeV, $|\eta^\mu| < 2.3$) using the results of fits to dimuon candidates in data corrected, candidate by candidate, for efficiencies using the fiducial weights, $w_{\text{fid}}$ defined in Eq. (2). These differential fiducial cross sections along with total uncertainties are shown in Figs. 8 and 9 and span 4 orders of magnitude across the $p_T$ range studied.
Integrating over all $p_T$ and both rapidity bins we find cross sections within the fiducial acceptance of the detector as shown in Table II. The results for the $Y(1S)$ are consistent with our previous measurement [8] but extend to a significantly higher $p_T$ and with increased precision.

Presenting the results in a restricted kinematic phase space removes any uncertainty due to the spin alignment of quarkonia. This allows unambiguous comparison of differential spectra with any theoretical approaches that can provide predictions with kinematic restrictions applied to the decay products of the $Y$.

NLO color-singlet [14] predictions [30] have previously been compared to differential $Y(1S)$ fiducial production cross sections [8] and were found to underestimate the measured production rates by approximately an order of magnitude and to not reflect the $p_T$ dependence of the data. This is not surprising as it has been known [16] for some time that higher-order corrections are both large and necessary in order to adequately describe quarkonium production at high $p_T$ with color-singlet terms. At this time, no color-singlet calculations beyond NLO are available for quarkonium production measurements quoted in a restricted muon acceptance, nor are color octet [17] or color evaporation [19] approaches currently able to account for the kinematics of leptons from the quarkonium decay. The fiducial measurements presented here are precise and free from any assumptions on the angular dependencies of the dimuon system, accurately reflecting the production dynamics in proton-proton collisions at $\sqrt{s} = 7$ TeV.

**B. Corrected cross sections**

We also calculate differential cross sections multiplied by the $Y \rightarrow \mu^+\mu^-$ branching fractions extrapolated to the full muon phase space within $|y^{\mu\mu}| < 2.25$. For these corrected cross sections, the results of fits to dimuon candidates in data are corrected, candidate by candidate, for efficiencies using the total weights, $w_{tot}$, defined in Eq. (2). Results are shown for the isotropic spin-alignment scenario in Figs. 10 and 11 as a function of $Y$ $p_T$ and $y$ for all three states and, integrated over all $p_T$ and both rapidity bins, in Table III.
Our results are consistent with measurements by CMS [6] and, in the small region of rapidity overlap from $2.0 < |y| < 2.25$, with LHCb [11]. These results allow us to test phenomenological models of $\Upsilon(nS)$ production not just at low $p_T$ (for complementarity with results from the Tevatron experiments) but in a newly-probed region of significantly boosted $\Upsilon$, where higher-order contributions become particularly important.

Figures 12–17 show the differential cross sections as a function of $p_T$ and rapidity for each of the $\Upsilon(nS)$ states in comparison with theoretical predictions. The effects of varying spin-alignment assumptions from the nominal assumption of isotropic muon angular distributions independent of $\theta^*$ and $\phi^*$ are indicated by a shaded band.

Clearly, spin alignment has a large effect on the $\Upsilon$ production cross sections, especially at low $p_T$, and, in particular, if there is a nontrivial azimuthal component to the spin alignment. New results [4,12] of $\Upsilon$ spin alignment from CDF and CMS suggest that the spin alignment is consistent with unpolarized production. Our central assumption of isotropic $\Upsilon$ decays is consistent with these results. Nevertheless, as these spin-alignment measurements are made at different center-of-mass energies or in a restricted phase space in both $p_T$ and rapidity with respect to measurements presented here, we provide the results under a variety of polarization scenarios so that the impact of spin alignment on the corrected cross sections can be quantified across the full range of study.

The contributions of the five polarization scenarios can be seen in the lower panes of each plot where the ratio of the differential cross section under these spin-alignment assumptions to the unpolarized scenario is shown. Across the whole $p_T$ range studied the envelope is bounded from above by the $T^+ + (\lambda_\theta = +1, \lambda_\phi = +1, \lambda_{\theta\phi} = 0)$ scenario with a maximal $\phi^*$ variation. From below, the cross section envelope is bounded by fully longitudinal spin alignment at very low $p_T$, with the $T^- + (\lambda_\theta = +1, \lambda_\phi = -1, \lambda_{\theta\phi} = 0)$ scenario resulting in the largest downward variation at $p_T \approx 4$ GeV. In this measurement we extend the $p_T$ range above 45 GeV where the maximal possible impact due to the unknown spin alignment of $\Upsilon$ is below $\pm 10\%$. This is significantly smaller than the theoretical uncertainties and is of similar magnitude to current
FIG. 8 (color online). Differential cross sections multiplied by the dimuon branching fraction, $d\sigma/dp_T dy \times \text{Br}(Y \rightarrow \mu^+ \mu^-)$, for central (top) and forward (bottom) rapidities, for $Y(1S)$, $Y(2S)$, $Y(3S)$ production within the fiducial acceptance. Points with error bars indicate results of the measurements with statistical uncertainties while shaded areas correspond to total uncertainties on the measurement, including systematic effects.

experimental uncertainties. As such, this region will offer a precision environment to compare future theoretical studies of $Y$ production to data.

In Figs. 12–14 a comparison is also made to two theoretical predictions of $Y$ production. The first [16] is a QCD-based calculation using the color-singlet mechanism [14], referred to as NNLO® CSM, and presumes that $Y$ meson production occurs via a color-singlet state and includes full corrections up to next-to-leading order (NLO), as well as some of the most important next-to-next-to-leading-order (NNLO) terms. This inclusion significantly modifies the prediction. The partial nature of the higher-order calculation limits the applicability of the calculation to values above a particular $Y$ $p_T$ threshold and increases the sensitivity of the prediction to the choice of renormalization and factorization scales. The second prediction, known as the color evaporation model [19,31], labeled as CEM, is a phenomenological model for inclusive $Y$ production based on quark-hadron duality. This model assumes that any heavy $Q\bar{Q}$ pair produced in the initial hard scattering evolves to a quarkonium state if its mass is below the threshold of open heavy-flavor meson pairs. Predictions of the CEM model involve a single constant that must be determined from corrected cross section measurements for each quarkonium state and use a $b$-quark mass of 4.75 GeV. As in the case of the CSM, divergences in the predictions restrict the applicability of the model at low $Y$ $p_T$. Uncertainties from factorization and renormalization scales are estimated from varying the scales independently up and down by a factor of 2 and additional uncertainties are estimated from varying the $b$-quark mass [32].

Color-singlet calculations at NLO/NNLO® predict a largely longitudinal polarization of direct $Y$ production at high $p_T$ (although the effect of feed-down introduces large uncertainties to this prediction). The color evaporation model offers no explicit prediction of the spin-alignment evolution of $Y$, but the nature of the model suggests no strong polarization should be observed as no single production mechanism dominates.

TABLE II. Integrated fiducial cross section measurements for $Y(nS)$. Uncertainties quoted represent statistical, systematic, and luminosity terms, respectively.

| State | Integrated fiducial cross sections $p_T^\mu > 4$ GeV, $|\eta^\mu| < 2.3$ | $\sigma_{\text{fid}}(pp \rightarrow Y) \times \text{Br}(Y \rightarrow \mu^+ \mu^-)$ | Range: $p_T^Y < 70$ GeV, $|y^Y| < 2.25$ |
|-------|-------------------------------------------------|-------------------------------------------------|---------------------------------|
| $Y(1S)$ | $1.890 \pm 0.007 \pm 0.095 \pm 0.074$ nb | | |
| $Y(2S)$ | $0.601 \pm 0.003 \pm 0.040 \pm 0.023$ nb | | |
| $Y(3S)$ | $0.304 \pm 0.003 \pm 0.021 \pm 0.012$ nb | | |
As can be seen in Figs. 12–14, the two models provide quite different descriptions of \( \Upsilon \) production. Predictions from CSM are for direct \( \Upsilon \) production only and so do not account for \( \Upsilon \) production that arises from feed-down from the production of higher \( \Upsilon \) states or from radiative decays of the \( \chi_{bJ}(nP) \). From previous measurements [33] the contribution of feed-down to \( \Upsilon(1S) \) production is known to be approximately 50%, but the \( p_T \) dependence of the feed-down is not well known and cannot be reliably predicted, and so no explicit correction is made to the CSM predictions shown. No correction is needed for the CEM as this is already an inclusive calculation. Feed-down contributions are expected to similarly contribute to \( \Upsilon(2S) \) production, but no measurement or reliable prediction for the relative contribution exists, so we do not apply a correction to the direct \( \Upsilon(2S) \) CSM predictions either. For \( \Upsilon(3S) \) there is no feed-down from higher \( \Upsilon \) states.

Recently, the ATLAS experiment discovered [34] the existence of a state or states interpreted as the \( \chi_{bJ}(3P) \) below the \( BB \) threshold that are expected to have a significant branching fraction for radiative decays into \( \Upsilon(3S) + \gamma \) and thus induce a feed-down contribution to \( \Upsilon(3S) \) (and other \( \Upsilon \) states). As the relative production and decay rates of these states are also as yet unknown, no correction is applied to the CSM predictions for \( \Upsilon(3S) \) production either.

For each of the three \( \Upsilon(nS) \) states, the NNLO* CSM predictions (considering also the additional normalization uncertainty due to the poorly known contributions from feed-down) fit our data well in the moderate \( p_T \) region but exhibit a steeper \( p_T \) dependence than seen in data. The predictions therefore significantly underestimate the cross section at high \( p_T \). Theoretical developments in the prediction of feed-down contributions may improve this description. CEM predictions appear to show a better match with data at high \( p_T \). These predictions underestimate the rate (favoring a smaller choice of renormalization/factorization scale or larger \( b \)-quark mass) and have

| State   | Integrated corrected cross sections | \( \sigma(pp \to \Upsilon) \times \text{Br}(\Upsilon \to \mu^+ \mu^-) \) |
|---------|-----------------------------------|-----------------------------------------|
| \( \Upsilon(1S) \) | \( 8.01 \pm 0.02 \pm 0.36 \pm 0.31 \text{ nb} \) | \( \rho_T^2 < 70 \text{ GeV}, |y| < 2.25 \) |
| \( \Upsilon(2S) \) | \( 2.05 \pm 0.01 \pm 0.12 \pm 0.08 \text{ nb} \) |
| \( \Upsilon(3S) \) | \( 0.92 \pm 0.01 \pm 0.07 \pm 0.04 \text{ nb} \) |
problems in modeling the shape of the spectrum, particularly at lower \( p_T \). Shape discrepancies cannot be accommodated within the uncertainties quoted as changes in the scale choice introduce correlated changes in the prediction as a function of \( p_T \).

Figures 15–17 show the variation of the production cross section as a function of absolute \( Y \) rapidity integrated...
across all $p_T$. The dependence on rapidity is relatively flat in the interval of rapidities in the ATLAS acceptance.

Variations between spin-alignment scenarios lead largely to a change in the normalization of the distributions with little variation in shape except at high rapidity. There, the $T^{++}$ scenario leads to an increase in the cross section with increasing rapidity, while the fully longitudinal scenario leads to a drop in cross section at high ($|y| \gtrsim 1.7$) rapidity.

FIG. 14 (color online). As for Fig. 12, but for $Y(3S)$ production.

C. Cross section ratios

From our differential cross section measurements, we explore the $p_T$ and rapidity dependence of $Y(2S)$ and $Y(3S)$ production relative to the $Y(1S)$ by deriving the ratios

FIG. 15 (color online). Differential cross sections multiplied by the dimuon branching fraction, $d\sigma/dy \times Br(Y \rightarrow \mu^+\mu^-)$, for $Y(1S)$ production extrapolated to the full phase space. Points with error bars indicate results of the measurements with total (statistical and systematic) uncertainties. The maximal envelope of variation of the result due to spin-alignment uncertainty is indicated by the solid band. The variations of the cross section measurement under the four anisotropic spin-alignment scenarios are shown in the lower pane as ratios to the unpolarized scenario.

FIG. 16 (color online). As for Fig. 15, but for $Y(2S)$ production.
for $|y| < 2.25$ with $n = 2, 3$. Such observables are sensitive to the magnitude and kinematic dependencies of feed-down contributions between the three $Y$ states. Results of the differential cross section ratio measurements are presented in Figs. 18 and 19.

These measurements are made under the assumption of unpolarized $Y(nS)$ mesons, and take into account statistical correlations between the fitted numbers of $Y(1S)$, $Y(2S)$, and $Y(3S)$ mesons. Systematic uncertainties are estimated by varying acceptance, efficiency, and fit model assumptions coherently in the numerator and denominator when calculating the ratios, thereby partially canceling uncertainties in the ratio. Luminosity uncertainties cancel entirely.

The measured $Y(nS)/Y(1S)$ ratios are relatively constant in the $0 < p_T < 5$ GeV interval at $\sim 20\%$ and $\sim 7\%$, respectively, for the $Y(2S)$ and $Y(3S)$. At higher $p_T$ a significant and steady rise in the relative production rates of higher $Y$ states is apparent, in agreement with measurements by CMS [6]. However, at the larger $p_T$ values (above

\[
\frac{d^2\sigma(pp \rightarrow Y(nS)/dp_Tdy}{d^2\sigma(pp \rightarrow Y(1S)/dp_Tdy} \times \frac{Br(Y(nS) \rightarrow \mu^+\mu^-)}{Br(Y(1S) \rightarrow \mu^+\mu^-)} = dp_T dy \tag{9}
\]

for $|y| < 2.25$ with $n = 2, 3$. Such observables are sensitive to the magnitude and kinematic dependencies of feed-down contributions between the three $Y$ states. Results of the differential cross section ratio measurements are presented in Figs. 18 and 19.

These measurements are made under the assumption of unpolarized $Y(nS)$ mesons, and take into account statistical correlations between the fitted numbers of $Y(1S)$, $Y(2S)$, and $Y(3S)$ mesons. Systematic uncertainties are estimated by varying acceptance, efficiency, and fit model assumptions coherently in the numerator and denominator when calculating the ratios, thereby partially canceling uncertainties in the ratio. Luminosity uncertainties cancel entirely.

The measured $Y(nS)/Y(1S)$ ratios are relatively constant in the $0 < p_T < 5$ GeV interval at $\sim 20\%$ and $\sim 7\%$, respectively, for the $Y(2S)$ and $Y(3S)$. At higher $p_T$ a significant and steady rise in the relative production rates of higher $Y$ states is apparent, in agreement with measurements by CMS [6]. However, at the larger $p_T$ values (above

\[
\frac{d^2\sigma(pp \rightarrow Y(nS)/dp_Tdy}{d^2\sigma(pp \rightarrow Y(1S)/dp_Tdy} \times \frac{Br(Y(nS) \rightarrow \mu^+\mu^-)}{Br(Y(1S) \rightarrow \mu^+\mu^-)} = dp_T dy \tag{9}
\]
of $30-40$ GeV) accessible for the first time with these measurements, evidence of a saturation in this rise is apparent, suggesting that we are probing a regime where direct production dominates over contributions from the decays of excited states. In contrast, the rapidity dependence of these production ratios is quite flat across the full $|y| < 2.25$ rapidity interval. Higher-order color-singlet calculations are not currently able to predict the evolution of these production ratios in $p_T^Y$ due to the significant feed-down contributions. At leading order in the quark velocity in the perturbative expansion, the production ratio of the direct contributions is proportional to the ratio of the squares of the magnitudes of the wave function at the origin (or the partial decay widths), multiplied by the branching fractions to dimuons for each of the states in question. The predicted ratios then are 36% for $Y(2S)/Y(1S)$ and 29% for $Y(3S)/Y(1S)$ for direct production. At high $p_T$, where the measured production ratio plateaus, the values are somewhat higher than these predictions suggesting that there is some enhancement (with respect to the simple picture above) of the $Y(2S)$ and $Y(3S)$ production relative to $Y(1S)$ production.

VII. CONCLUSIONS

We have measured differential production cross sections and relative production rates for $Y(1S)$, $Y(2S)$, and $Y(3S)$ mesons in $pp$ collisions at $\sqrt{s} = 7$ TeV at the LHC up to $p_T^Y < 70$ GeV in the rapidity interval $|y|^7 < 2.25$. The possible impact of the $Y$ spin alignment on these measured spectra is also quantified. These measurements are compatible with measurements by the CMS and LHCb collaborations. We have measured integrated corrected cross sections multiplied by the $Y \rightarrow \mu^+\mu^-$ branching fractions, within the rapidity region $|y|^7 < 2.25$ of 8.01 ± 0.02 ± 0.36 ± 0.31 nb, 2.05 ± 0.01 ± 0.12 ± 0.08 nb, and 0.92 ± 0.01 ± 0.07 ± 0.04 nb for the $Y(1S)$, $Y(2S)$, and $Y(3S)$, respectively. Uncertainties correspond to statistical, systematic, and luminosity measurement effects.

These cross section estimates assume unpolarized production corresponding to $\lambda_\theta = \lambda_\phi = \lambda_{\theta\phi} = 0$ in Eq. (3). If the production polarization is fully transverse or longitudinal with no dependence on the azimuthal decay angle $\phi^*$, corresponding to $\lambda_\theta = \pm 1$, $\lambda_\phi = \lambda_{\theta\phi} = 0$, the integrated cross sections may vary by up to (19, −23)%, (18, −21)%, and (17, −19)%, respectively, for the $Y(1S)$, $Y(2S)$, and $Y(3S)$. However, acceptances corresponding to certain nonzero values of $\lambda_\phi$ can become extremely low, especially at low transverse momenta of the muon pair. This would lead to a significant increase of the corrected cross sections in these configurations, up to +217%, +155%, and +126% for the three $Y$ states.

We compare our differential cross section results to predictions from two theoretical approaches describing $Y$ production. Our measurements find both the NNLO* CSM and the CEM predictions have some problems in describing the normalization and shape of the differential spectra. In particular, NNLO* dramatically underestimates the rate at high transverse momenta, where the data tend to agree better with the CEM. The inclusion of $P$-wave feed-down contributions in the theoretical calculation may help to improve the description. Large scale uncertainties in these predictions allow possible contributions from color-octet terms to contribute to the production rate in addition to singlet diagrams. The differential production ratios indicate that the increase in the production of higher $Y$ states as a function of $p_T^Y$ relative to the $Y(1S)$ observed previously begins to saturate at $30-40$ GeV. Above $\sim 40$ GeV, the envelope of possible variations in the differential cross sections due to spin alignment is reduced to below $\pm 10\%$. This, along with the expected reduction in feed-down contributions, results in a relatively well-controlled region in which to study quarkonium production without the dominant experimental and theoretical effects that complicate such studies at lower $p_T$.

ACKNOWLEDGMENTS

[20] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector, and the $z$ axis along the beam line. The $x$ axis points from the IP to the center of the LHC ring, and the $y$ axis points upwards. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam line. Observables labeled transverse are projected into the $x$-$y$ plane. The pseudorapidity is defined in terms of the polar angle as $\eta = -\ln \tan(\theta/2)$. Rapidity is defined as $y = \frac{1}{2} \ln \frac{p_z + E}{p_z - E}$, where $E$ is the energy and $p_z$ is the momentum parallel to the beam axis.
