Abstract

Objective. Brain–computer interfaces (BCIs) constitute a promising tool for communication and control. However, mastering non-invasive closed-loop systems remains a learned skill that is difficult to develop for a non-negligible proportion of users. The involved learning process induces neural changes associated with a brain network reorganization that remains poorly understood.

Approach. To address this inter-subject variability, we adopted a multilayer approach to integrate brain network properties from electroencephalographic and magnetoencephalographic data resulting from a four-session BCI training program followed by a group of healthy subjects. Our method gives access to the contribution of each layer to multilayer network that tends to be equal with time.

Main results. We show that regardless the chosen modality, a progressive increase in the integration of somatosensory areas in the α band was paralleled by a decrease of the integration of visual processing and working memory areas in the β band. Notably, only brain network properties in multilayer network correlated with future BCI scores in the α² band: positively in somatosensory and decision-making related areas and negatively in associative areas.

Significance. Our findings cast new light on neural processes underlying BCI training. Integrating multimodal brain network properties provides new information that correlates with behavioral performance and could be considered as a potential marker of BCI learning.

1. Introduction

Learning is a complex phenomenon that can be characterized by changes in regional associations and therefore in brain network organization [1]. Changes following learning have been revealed in language [2, 3] and in motor skill acquisition with resting-state fMRI recordings [4, 5]. In the case of motor learning, studies that focus on functional connectivity have demonstrated changes induced by skill acquisition [5–9]. From a network perspective, a large number of metrics characterizing network properties have been considered to capture the process of motor acquisition. In [10], the motor performance improvement was associated with an increase of clustering coefficients, a higher number of network
connections, an increased connection strength and shorter communication distances. Another approach consists of using a single metric that measures subnetwork segregation: modularity [11], already used as a marker of brain plasticity [12] and motor learning [13]. Motor skill acquisition induced an autonomy of sensorimotor systems and individual differences in the amount of learning could be predicted by the release of cognitive control hubs in frontal and cingulate cortices [14].

Mastering non-invasive closed-loop systems is a learned skill that requires several training sessions to achieve control of the device. Recent studies suggest that the involved learning process is analogous to cognitive or motor skill acquisition in the case of brain–computer interface (BCI) [15]. It may induce behavioral modifications and neural changes within trained brain circuits in neurofeedback that last for several months after training [16]. Changes at the neuronal level, during the learning process, have also been observed and simulated [17]. The recruitment of areas beyond those targeted by BCI has been observed during skill acquisition [18, 19], and a decrease in the global efficiency index in the higher-beta frequency range with the practice of MI [20] suggests the involvement of a distributed core of brain areas while learning. From a theoretical perspective, the existence of a core, a group of tightly connected nodes, surrounded by a poorly connected periphery is crucial for the integration of information between remote network components [21, 22]. Previous studies have demonstrated the utility of using multilayer models of networks [23, 24] to study the relationship between structure and function in the human brain. The identification of core-periphery structures in brain networks can be significantly enriched by adding multiple levels of connectivity [25, 26]. In particular, combining multifrequency or multimodal neuroimaging data from a network perspective can reveal higher-order topological properties that cannot be detected by simple single-layer network approaches [25, 27–32]. Magnetoencephalography (MEG) and electroencephalography (EEG) are complementary in terms of sensitivity towards source depths and conductivity, but also in terms of dipole orientation detection [33–38]. As a result, their combination could provide valuable information, and has proven to enhance subjects’ mental state discrimination in BCI [39].

On the above mentioned elements, we hypothesized that integrating information from EEG and MEG data, allow a better description of the core-periphery changes occurring during a motor imagery-based BCI training in a group of healthy subjects. Such an enriched description could reveal fresh insights into learning processes that are difficult to observe at the single layer level and eventually improve the prediction of future BCI performance.

2. Materials and methods

2.1. Participants and experiment

We included twenty healthy, and BCI naive, subjects (aged 27.5 ± 4.0 years, 12 men). All right-handed, they participated in a 4 session-based BCI training during two weeks. According to the declaration of Helsinki, a written informed consent was obtained from subjects after explanation of the study, which was approved by the ethical committee CPP-IDF-VI of Paris. The EEG-based BCI consisted of a two-target box task [40]. The subjects were instructed to control the vertical position of a moving cursor by modulating the neural activity in the α (8–12 Hz) and/or β (14–29 Hz) frequency bands. Each session was divided into two phases:

(a) The training phase consisted of five consecutive runs, of 32 trials each, without any feedback. For a given trial, the first second consisted of the inter-stimulus interval (ISI) followed by 5 s of target presentation. To elicit the (EEG electrodes; frequency bins) couples that best discriminate the subjects’ mental state over the left motor area and within the mu-beta frequency ranges, we computed contrast maps that relied on the R-square metric [41].

(b) The testing phase consisted of six runs, of 32 trials each, with a cursor feedback. Similarly to the training phase, for a given trial, we had one second of ISI, while the target was presented throughout the subsequent five seconds. The visual feedback, displayed from $t = 3$ s to $t = 6$ s, consists of a moving cursor. The features, i.e. power spectra estimated at the (EEG electrodes; frequency bins) couples selected during the training, were classified by using the Linear Discriminant Analysis method. All the results presented in the following sections relied on the analysis performed on the testing data.

To perform the experiments, we used a 74 EEG-channel system, with Ag/AgCl passive sensors (Easycap, Germany) placed according to the standard 10-10 montage. The reference was located at the mastoids and the ground electrode was placed at the left scapula. We kept the impedances lower than 20 kOhms. The MEG system consisted of 102 magnetometers and 204 gradiometers (Elekta Neuromag TRIUX MEG system). E/MEG registrations were performed simultaneously in a magnetic shielded room with a sampling frequency of 1 kHz and a bandwidth of 0.01–300 Hz. The subjects were seated with palms facing upward in front of a 90 cm distant screen. To ensure that no forearm movements were performed, experts visually inspected electromyogram signals recorded from the subject’s right arm during the experiment. During the sessions, BCI feedback relied on EEG signals transmitted to the
BCI2000 toolbox [41] via the Fieldtrip buffer [42]. Individual T1 sequences have been obtained using a 3T Siemens Magnetom PRISMA after the fourth session to ensure accurate head models [43]. These registrations consisted of a 15 min resting-state task. A preprocessing of the images was performed via the FreeSurfer toolbox [44] and directly imported (15,002 vertices) to the Brainstorm toolbox. To provide co-registration with the anatomical MRI, we digitized the location of the EEG electrodes and three landmarks (nasion, left and right preauricular points) with the FastTrak 3D digitizer (Polhemus, Inc., VT, USA). These locations were aligned with the MRI using the Brainstorm toolbox [45]. A more detailed description of the experiments is proposed in [46].

2.2. Data analysis
2.2.1. M/EEG processing
After a first preprocessing step that consisted of an application of the temporal extension of the Signal Space Separation to MEG signals to remove environmental noise [47], M/EEG data were downsampled to 250 Hz and processed via the Independent Component Analysis [42, 48] to remove ocular and cardiac artifacts. Then, data were segmented into 7 s epochs, corresponding to the trial length.

Source reconstruction was performed by applying the Boundary Element Method [49, 50] to obtain the individual head model, followed by the estimation of the sources with the weighted Minimum Norm Estimate [45, 51–53]. A more detailed description of the applied preprocessing steps is proposed in [46].

To compute the power spectra within the individual anatomical space, we used the Welch method. A time window of 1 s and a window overlap ratio of 50% was applied during the feedback period (i.e. from \( t = 3 \) s to \( t = 6 \) s) to obtain the cross-spectral estimation for each trial, session, and subject. Then, for each region of interest (ROI) from the Destrieux atlas [54], we took into account the first principal component of the power spectra computed over the dipoles. For each layer (or modality here) \( f \) and frequency band \( l \), we estimated the functional connectivity networks by computing the imaginary coherence between each pair of ROIs (\( N = 148 \)) [55], resulting in \( 148 \times 148 \) adjacency matrices \( A_{lf} \).

2.2.2. Network analysis and statistics
Similarly to [26, 32], to obtain the multilayer or multiplex brain networks \( M_f \) for a given frequency band \( f \) from the adjacency matrices \( A_{lf} \), we aligned the EEG and MEG connectivity networks as follows:

\[
M_f = A_{lf}, \forall l \in \{\text{EEG, MEG}\}. \tag{1}
\]

To study properties associated with a core-periphery organization, for a given layer (i.e. modality here), we filtered the associated adjacency matrix \( A_{lf} \) to keep the strongest weights by applying a broad range of thresholds corresponding to the average node degree \( k = 1 \) to \( k = N - 1 \). For each threshold \( k \), to determine whether a node \( i \) belongs to the core, we computed the multiplex core-periphery of the filtered network by calculating its richness defined as follows:

\[
\mu_i = \sum_{l=1}^{L} \delta_{i,l}^p,
\]

where \( L \) corresponds to the number of layers (\( L = 2 \)), \( \delta_{i,l}^p \) corresponds to the strength of the node \( i \) in the \( l \)th layer (i.e. the sum of the \( l \)th row of the matrix \( A_{lf} \)), and \( c \) corresponds to the \( l \)th component of the vector \( c \) that represents the contribution of each layer (ranging from 0 to 1). To take into account only the links of node \( i \) that are associated with nodes of higher richness, we decomposed the richness function as follows:

\[
\mu_i = \mu_i^{-} + \mu_i^{+}.
\]

We finally computed the multiplex coreness [26] \( C_i \) of each node \( i \), independently from any other consideration, by determining the number of times the node \( i \) belongs to the core over all the \( k \) tested thresholds, as follows:

\[
C_i = \frac{1}{N-1} \sum_{k=1}^{N-1} \delta_{i,k}^p,
\]

where \( \delta_{i,k}^p = 1 \) if node \( i \) belongs to the core for the threshold \( k \), and 0 otherwise. To obtain the coreness associated with a specific layer, one can simply modify the vector \( c \) in equation (3) so that the component not related to the given modality is equal to zero. For each subject, session and frequency band, we optimized the choice of the components of the vector \( c \) by using the Particles Swarm Optimization and Statistical Analysis (PSO) algorithm [32, 56]. In our case, the Fisher’s criterion \( F(c) \), chosen to maximize the difference between the conditions, was defined as follows:

\[
F(c) = \frac{(\langle C^{\text{cond}}(c) \rangle - \langle C^{\text{rest}}(c) \rangle)^2}{(\langle C^{\text{cond}}(c) \rangle)^2 + (\langle C^{\text{rest}}(c) \rangle)^2}, \tag{5}
\]

where \( \langle C^{\text{cond}}(c) \rangle \) is the averaged coreness computed over the nodes \( i \) in the condition \( \text{cond} \) and

\[
\langle s^{\text{cond}} \rangle^2 = \sum_{i \in \{1..N\}} (C_i^{\text{cond}} - \langle C^{\text{cond}}(c) \rangle)^2, \tag{6}
\]

where \( C_i^{\text{cond}} \) corresponds to the coreness computed in node \( i \) in the condition \( \text{cond} \).

To study the variation of coreness between conditions, we defined the relative coreness (\( \Delta C \) as

\[
\Delta C = \frac{C_i^{\text{cond}} - C_i^{\text{rest}}}{C_i^{\text{rest}}}, \tag{7}
\]

where \( C_i^{\text{cond}} \) and \( C_i^{\text{rest}} \) are the coreness computed in the condition \( \text{cond} \) and the rest condition, respectively.
\[ \Delta C = C^{MI} - C^{Rest} \]

To compute the multiplex core-periphery properties, we used the Brain Connectivity Toolbox [57] and the Matlab code available at [https://github.com/brain-network/bnt](https://github.com/brain-network/bnt).

To take into account the subjects’ specificity, we used customized definitions of the \(\alpha\) and \(\beta\) bands [58], that rely on the individual alpha frequency (IAF) [59], obtained from a 3 min resting state recording. The \(\alpha_1\) ranges from IAF \(- 2\) Hz to IAF, \(\alpha_2\) from IAF to IAF + 2 Hz, \(\beta_1\) from IAF + 2 Hz to IAF + 11 Hz and \(\beta_2\) from IAF + 11 Hz to IAF + 20 Hz. Preliminary results did not show particularly significant effects in \(\theta\) and low \(\gamma\) bands. Therefore, only results obtained within the \(\alpha\) and \(\beta\) frequency bands are presented here.

After plotting quantile-quantile plots and performing the Shapiro–Wilk test [60], it became clear that the coreness values were not normally distributed. Thus, to evaluate the session and the modality effect on the coreness and its associated properties, we fitted and tested an ANOVA using 5000 permutation-tests (ImPerm package in R). Correlations between BCI scores and coreness were estimated via the use of repeated-measures correlations (rmcorr package in R [61]).

Results obtained from paired \(t\)-tests between conditions (to assess the condition effect) and from repeated-measures correlations referred to a statistical threshold of 0.05 corrected for multiple comparisons by adopting a false discovery rate criterion [62], which is a method extensively used in biological studies [63–65].

3. Results

Before studying the evolution of network properties over sessions, we first determined whether a learning effect was actually present. We applied a one-way repeated non-parametric ANOVA on the BCI accuracy scores averaged across the runs of each session with the session number as the intra-subject factor (figure 1(A)). Results confirmed that a learning effect was present at the group level (\(F(3,57) = 13.9, p = 6.56 \times 10^{-7}\)). In particular, sixteen subjects out of 20 achieved the ability to control the moving cursor by the end of the training, with accuracy scores above the chance level of 57% [66].

As explained in the previous section, we started our analysis by using the adjacency matrices obtained from [46] to build single layer networks (figure 1(B), see supplementary materials figures S1 and S2 (available online at [stacks.iop.org/JNE/18/056002/mmedia])), and we investigated in which extent integrating the network properties obtained from EEG and MEG would be beneficial to the search of BCI training markers.
Figure 2. Single and multilayer provided information (A) Evolution of single layer and multiplex coreness values over BCI training in the MI condition. For a given axis associated with a single brain lobe, we plotted the median coreness value obtained across the subjects and the ROIs that belong to the lobe, respectively in EEG, MEG and multiplex (mux). The first line corresponds to the evolution within the $\alpha_2$ frequency band and the second line corresponds to that within the $\beta_1$ frequency band. 
(B) Evolution of the relative coreness ($\Delta C$) over the sessions. On the X axis are represented the $\Delta C$ values, averaged over the subjects, obtained with the EEG layer; on the Y axis are presented the values obtained with the MEG layer. The color of the markers is associated with the values obtained with multiplex. Each marker corresponds to a given ROI.

As a preliminary step, we studied the evolution of the attributed weights across sessions (figure 1(C), see supplementary materials figure S3). We observed that the main session and modality effects occurred within the $\alpha$ and the $\beta$ bands, with significant interaction effects in $\alpha_2$ and $\beta_1$ bands (two-way ANOVA, respectively $p = 0.022$ and $p = 0.027$). In these bands, we observe similar trends. In session 1, $\omega_{\text{MEG}}$ is larger than $\omega_{\text{EEG}}$; then, the opposite effect occurred before the convergence to 0.5 at session 4. This final convergence to 0.5 indicates a progressive equal contribution of the two modality layers on the regional multiplex coreness.

3.1. Multiplex core-periphery provides additional information
We studied single and multiplex (mux) coreness trends over sessions in the MI condition (figure 2(A)). Similar tendencies were observed in the different modalities both within the $\alpha$ and $\beta$ frequency ranges (see supplementary materials figure S4). In particular, we observed that the highest values of MI coreness were obtained in ROIs that belongs to the frontal lobe. In $\alpha_2$, we obtained a progressive increase of the median value within the frontal lobe, especially in mux (see figure 2(A)). The second most important lobe was the lateral one, in particular for EEG and
We noticed an increase of the median value obtained within parietal lobe in MEG. In $\beta_1$, these observations were even clearer with an increase of the values obtained within the lateral lobes in EEG and mux, whereas values within in the parietal lobe were stable and those obtained within the occipital lobe were negligible. These first observations showed that specific brain lobes presented clear variations of coreness values depending on the considered modality (for a more detailed presentation of the distribution of coreness values in the MI condition, see supplementary materials figure S5, and for a presentation of multiplex coreness values, see and supplementary materials figure S6).

The scatter plots represented in (figure 2(B)) are associated with the relative coreness ($\Delta C$) values obtained for each single layer (X and Y axis) and also for the multiplex. Within the $\alpha$ band, we observed that the distribution of points progressively followed a linear relationship between EEG and MEG $\Delta C$ values, meaning a non-negligible part of the information is shared by these modalities at the end of the training. Within the $\beta$ band, we noticed an absence of a linear relationship between EEG and MEG, meaning that the two single layers shared less common information.

Furthermore, we assessed the modality effect associated with $\Delta C$ via a one-way ANOVA, with the modality taken as the intra-subject factor. In the $\alpha - \beta$ ranges the parahippocampal gyrus significantly differed between modalities ($p < 0.030$) associated with visual functions [67]. Within the $\alpha$ frequency range, we observed a significant modality effect in the middle-anterior part of the cingulate gyrus ($p < 0.030$) involved during decision making and memory consolidation [68]. In the $\beta_1$ band, the long insular gyrus, also associated with decision making [69] presented a significant difference in terms of modality ($p < 0.001$). The presented modality effects were driven by a significant difference between EEG and MEG relative coreness (Tukey post-hoc multiple pairwise comparisons, $p$-values adjusted via the Holm method $p < 0.050$).

We also evaluated the information of interest provided by the multiplex with respect to single layers by statistically comparing the coreness of the MI versus the Rest conditions with a paired t-test ($p < 0.021$, see supplementary materials tables S1–S3). We observed two opposite trends depending on the frequency range. In $\alpha_2$, at the single layer level, no consistent significant ROIs were obtained whereas we observed an increased involvement of the gyrus rectus with the multiplex with the training ($p < 0.01$ at session 4). This brain area is known to be associated with decision making involving a reward [70]. Within the $\beta$ ranges, we observed a lower number of ROIs showing a significant condition effect. In $\beta_1$, at the single layer, no significant ROIs ($p < 0.021$) were obtained during the first session whereas the multiplex presented three: short insular gyri (involved in motor planning [69]), planum polare of the superior temporal gyrus (deductive reasoning [71]), and the gyrus rectus (see supplementary materials table S3).

In the next sections, to directly account for the variations of coreness between conditions, we will focus our study on the relative coreness $\Delta C$. Furthermore, in order to take into account the most informative ROIs, we pre-selected the areas that show a significant condition effect at least once during the training before performing the analysis presented in the subsequent sections.

### 3.2. Relative coreness changes during training

To provide a more detailed description of the evolution of the relative coreness over training, we performed a one-way ANOVA for each layer separately (see supplementary materials figure S8).

We observed that $\Delta C$ presented a significant session effect involving different brain areas (figure 3(A), see supplementary materials figure S7). Within the $\alpha_2$ range, a significant session effect was observed in EEG mostly within the long insular gyrus and the gyrus rectus; a significant session effect was observed in MEG in the supramarginal gyrus (working memory and motor planning [72]); and in the multiplex a significant session effect was observed in areas involved during motor planning and working memory (orbital part of the inferior frontal gyrus and subcallosal gyrus) [73–75] and in learning complex motor skills (middle-posterior part of the cingulate gyrus)[76]. In each case, we obtained an increase of $\Delta C$ with training (see figure 3(A) and supplementary materials figure S7). Within the $\beta_1$ range, a significant session effect was observed in EEG within the inferior temporal gyrus (dual working memory task processing) and in the multiplex in areas associated with visual processing (superior temporal gyrus), working memory (middle frontal gyrus), and motor planning (short insular gyri). In the multiplex, most of the ROIs showing a significant session effect present a decrease of $\Delta C$ with training (see figure 3(B)).

### 3.3. Multiplex relative coreness correlated with future BCI performance

For the sake of simplicity, we will present our results only with relative coreness within the $\alpha_2$ band were the most significant observations were made. For a complete presentation of the results, see supplementary materials figures S10 and S11.

We observed that the relative coreness presents a significant correlation with the BCI scores, within a larger number of significant ROIs in the multiplex in comparison with EEG or MEG (see supplementary materials figure S10). In EEG, negative correlations
Figure 3. Relative coreness changes during training. (A) ROIs showing a significant session effect (one-way ANOVA, \( p < 0.05 \)). (B) Distribution over the training in the multiplex. Only the ROIs that present a significant session effect are represented (one-way ANOVA, \( p < 0.05^*, p < 0.01^{**}, p < 0.001^{***} \)).

were obtained within the posterior-ventral part of the cingulate gyrus, the fronto-marginal gyrus (\( p < 0.01 \)) (respectively involved during learning a complex motor skill and working memory [76–79]) and a positive correlation within the middle temporal gyrus (involved during the observation of motion [80]). In MEG, a positive correlation was observed within the triangular part of the inferior frontal gyrus (\( p < 0.01 \), involved during motor response inhibition and working memory [73–75]) and a negative correlation within the cuneus (involved during visual processing [81]). In the multiplex networks, positive correlations were obtained in regions involved respectively during motor tasks and motor imagery with working memory tasks (subcentral gyrus, superior parietal lobule, and subcallosal gyrus) [7, 79, 82, 83]. A negative correlation was obtained within the gyrus rectus (decision making involving reward).

To assess whether relative coreness could be associated with future BCI performance, we estimated the correlation between \( \Delta C \) in session \( i \) and the BCI score obtained in session \( i + 1 \). We observed significant correlations only with multiplex within the \( \alpha_2 \) band (figure 4). More precisely, a positive correlation (\( p < 0.01 \)) was observed in the gyrus rectus, the subcentral gyrus, but also the long insular gyrus (involved during somatosensory tasks [69]). A negative correlation was obtained in the superior occipital gyrus associated with visual processing (in blue in figure 4) [84].

4. Discussion

Controlling a BCI remains a learned skill that is difficult to develop for a non-negligible number of users (15%–30%) [85]. Previous studies dedicated to elicit neural dynamics underlying BCI skill acquisition in primates [86, 87] and humans [19, 20] suggest the presence of a distributed and dynamic network of cortical areas above the motor-related ones. However, the evolution of such brain networks over training is largely unknown mainly because of a lack of longitudinal studies based on BCI paradigms [88]. Our protocol relied on reinforcement learning [89] based on a well-known two-target box task [40] where a training effect has been obtained. In this study, we were particularly interested in understanding the brain network macroscale changes during the learning process. A few number of works, relying on BCI protocols and involving healthy subjects, have previously addressed this question [46, 90].

4.1. Tracking core-periphery changes

It has been proved that core-periphery properties could be a valuable tool to track brain reorganization associated with cognitive processes [91] but also disorders [92, 93]. In this study, we worked with the coreness, a concise and robust metric that enables us to assess the likelihood to belong to the core of a network [25, 26]. Regardless of the modality, opposite trends were obtained within the \( \alpha \) and \( \beta \) ranges in terms of the evolution of the discrimination between conditions and of the \( \Delta C \) values with time (see supplementary materials figure S8 and tables S1–S3). Nevertheless, these observations were particularly true for the multiplex involving \( \alpha_2 \) areas associated with somatosensory tasks and motor planning, and \( \beta_1 \) in areas associated with visual processing and working memory (see figure 3).

The \( \alpha \) activity is known to be linked to the inhibition of task-irrelevant areas [94–96]. If \( \beta \)
Repeated correlations between BCI performance of the subsequent session and the multiplex relative coreness in the alpha2 band. At the center, we plotted the r-values projected onto the scalp (p < 0.05). On either side, scatter plots obtained from the two ROIs showing the highest r-values (p < 0.01). The dashed line represents the overall regression plot and the paralleled lines correspond to the fit to each subject’s data taken separately.

4.2. Layer comparisons

The complementary role of EEG and MEG has been proved at different levels: dipole orientation and source localization [36, 38, 102] and subjects’ mental state classification [39]. However, such complementarity has been poorly studied at the network level despite some interesting results in functional connectivity [103]. To better capture network changes at different time or spatial scales, one can use multilayer models of networks [23, 24]. This approach enabled for example, in the time domain, to predict the relative learning rate via the flexibility [13] in motor skill acquisition, but also to identify core-periphery changes in Alzheimer disease via a multimodal approach combining structural and functional networks [25, 26, 32].

Here, based on previous work where MEG and DTI were combined [32], we integrated modalities knowing the contribution of each of them in such a way as to ensure the highest separation between conditions. These weights tended to converge to 0.5 (see figure 1(C)), meaning that the two modalities provided similar contribution to the multiplex network towards the end of the BCI training. This finding suggests that the two modalities are as important to discriminate MI and Rest conditions in the multiplex at the end of the training. As a result, the multiplex appeared to present a larger and more robust condition effect with respect to EEG and MEG (see supplementary materials figure S7 and tables S1–S3). However, the attributed weights did not present a significant correlation with BCI performance. The approach proposed here also raised the possibility to compare results obtained from different layers. In particular, in α2, we obtained a progressive linear relationship between EEG and MEG relative corenesses with time over all the ROIs (see figure 2(B)). This result suggests that, at a global level, MEG and EEG capture similar task-related processes occurring during the BCI experiment, especially at the end of training. The modality effects, suggested in figure 2(A), and actually observed at the relative coreness level, were driven by a significant difference between EEG and MEG relative corenesses. This effect was mostly observed in areas associated with decision making and memory consolidation, highlighting the utility to combine MEG and EEG networks to better capture mechanisms underlying learning process.

4.3. Markers of cognitive performance

Identifying neural features underlying BCI performance is crucial to design optimized and individualized BCI architectures [104, 105]. Among the elicited markers are psychological and demographical traits [106]. From a neurophysiological perspective, previous studies identified power spectra in θ, α and γ bands as potential predictors of BCI scores [107, 108]. In our study, the most significant
results were obtained in $\alpha_2$ and $\beta_1$ frequency bands. Recent findings proved that functional connectivity could correlate with the user’s performance [39, 109, 110]. However, these studies were associated with a single session BCI performance. In a recent work, we showed that the regional connectivity strength of specific associative cortical areas could explain the BCI performance in the same session but also the future learning rate [46]. Here, we were particularly interested in identifying markers of BCI performance at the core-periphery network level.

If EEG, MEG, and multiplex presented associations with BCI scores, only the latter presents a significant correlation with the BCI performance of the next session based on the relative coreness within the $\alpha_2$ band (see supplementary materials figures S10 and S11). Two trends were again observed: a positive correlation in areas respectively involved during decision making and somatosensory tasks (gyrus rectus, subcentral gyrus, and long insular gyrus) and a negative correlation in the superior occipital gyrus associated with visual processing (see figure 4). These findings are in line with previous studies that reported a larger clustering coefficient in the gyrus rectus associated with a higher nodal betweenness centrality (NBC) in sensorimotor areas and a reduced NBC in visual areas in the context of motor training [111, 112]. Altogether, these results support the hypothesis that sensorimotor areas and associative areas play a crucial role in motor sequence learning as well as in abstract task learning [7, 113–115] and that cognitive processes involved in the supervisory attentional system [116, 117] are important to perform MI tasks [118] and motor learning [119–122].

4.4. Caveats and perspectives

The temporal window of study is a crucial matter when considering a longitudinal experimentation, especially in the BCI domain. Our participants followed a four-session-training program, within two weeks. This temporal window might not be sufficient to observe the full learning process [88, 123]. However, our results constitute the first observations of a training process at the core-periphery level. Further studies based on longer BCI training are necessary to assess whether our observations could be still verified on a larger temporal scale.

This work could pave the way to further explore of the integration of M/EEG network information to better understand neural mechanisms underlying learning but also task performance in particular in the use of BCI in a clinical context. However, before considering multimodal BCIs in routine, further developments are required to increase MEG portability. The use of new generation of MEG sensors (i.e. optically-pumped magnetometers) could meet this need [124–127].

5. Conclusion

In this work, we have proved that studying the network integration changes at the single and multilayer levels provides additional information to characterize dynamic brain reorganization during BCI training. We found that a progressive increase of the integration of somatosensory areas in the $\alpha$ band was paralleled by a decrease of the integration of visual processing and working memory areas in the $\beta$ band. More importantly, these changes were more visible in multiplex in which brain network properties correlated with future BCI scores in the $\alpha_2$ band. Taken together, our results cast new light on brain network reorganization occurring during BCI training and more generally during human learning.

Data availability statement

The data generated and/or analyzed during the current study are not publicly available for legal/ethical reasons but are available from the corresponding author on reasonable request.

Acknowledgments

This work was partially supported by French program ‘Investissements d’avenir’ ANR-10-IAIHU-06; ‘ANR-NIH CRCNS’ ANR-15-NEUC-0006-02 and by NICHD 1R01HD086888-01. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript. This work was performed on a platform of France Life Imaging network partly funded by the grant ‘ANR-11-INBS-0006’.

Citation diversity statement

Recent work in several fields of science has identified a bias in citation practices such that papers from women and other minority scholars are under cited relative to the number of such papers in the field [128–132]. Here we sought to proactively consider choosing references that reflect the diversity of the field in thought, form of contribution, gender, race, ethnicity, and other factors. We used automatic classification of gender based on the first names of the first and last authors [132, 133], with possible combinations including man/ man, man/woman, woman/man, and woman/woman. Code for this classification is open source and available online [133]. By this measure (and excluding self-citations to the first and last authors of our current paper), our references contain 4.96% woman (first)/woman (last), 13.24% man/woman, 16.34% woman/man, and 65.47% man/man. Second, we obtained predicted racial/ethnic category of the first and last author of each reference by databases that store the probability of a first and last name being carried by an author.
of color [134, 135]. By this measure (and excluding self-citations), our references contain 12.99% author of color (first)/author of color (last), 14.83% white author/author of color, 21.91% author of color/white author, and 50.26% white author/white author. We look forward to future work that could help us to better understand how to support equitable practices in science.

**Authors contributions**

M C, D S, N G, L H, S D, D S B and F D V F initiated research; M C C, M C, D S, L H, D S B and F D V F designed research; M C C, D S and L H performed research; M C C, D S, L H and A E K contributed analytic tools; M C C and A E K analyzed data; and M C C, D S B, and F D V F wrote the paper. All authors revised and approved the manuscript.
