A novel, selective and sensitive switch-on fluorescent sensor for Hg$^{2+}$ and switch-off fluorescent probe for biothiols was developed by using [Ru(bpy)$_2$(pip)]$^{2+}$ as the signal reporter and graphene oxide (GO) as the quencher. Due to the affinity of GO towards single-stranded DNA (ss-DNA) and [Ru(bpy)$_2$(pip)]$^{2+}$, the three components assembled, resulting in fluorescence quenching. Upon addition of Hg$^{2+}$, a double-stranded DNA (ds-DNA) via T–Hg$^{2+}$–T base pairs was formed, and [Ru(bpy)$_2$(pip)]$^{2+}$ intercalated into the newly formed ds-DNA. Then, [Ru(bpy)$_2$(pip)]$^{2+}$ and ds-DNA were removed from the surface of GO, resulting in the restoration of fluorescence. Subsequently, upon addition of biothiols, Hg$^{2+}$ was released from ds-DNA, due to the higher affinity of Hg$^{2+}$ to the sulfur atoms of biothiols, which could induce ds-DNA unwinding to form ss-DNA. Then ss-DNA and [Ru(bpy)$_2$(pip)]$^{2+}$ were adsorbed on the surface of GO, the fluorescence of [Ru(bpy)$_2$(pip)]$^{2+}$ was quenched again. Therefore, the changes in emission intensity of [Ru(bpy)$_2$(pip)]$^{2+}$ directly correlated to the amount of detection target (Hg$^{2+}$ or biothiols) in solution. The assay exhibited high sensitivity and selectivity, with the limits of detection for Hg$^{2+}$, cysteine (Cys) and glutathione (GSH) to be 2.34 nM, 6.20 nM and 4.60 nM, respectively.

Hg$^{2+}$ is one of the most toxic heavy metals. Even at low concentration, it is a threat to the human health and environment due to its ability of accumulation in ecological system. Mercury poisoning induces a wide variety of serious human diseases, including brain damage, kidney failure, and various cognition and motion disorders. Therefore, the interest in developing rapid, specific, and cost-effective methods to detect Hg$^{2+}$ is steadily growing. Much effort has been made to develop the Hg$^{2+}$ sensors, including electrochemical sensors, colorimetric sensors, and fluorimetric sensors. Among them, functional nucleic acid sensors have recently received considerable attention, based on the fact that thymine base pairs can selectively capture Hg$^{2+}$ to form T–Hg$^{2+}$–T base pairs. However, most of the existing fluorescent probes rely on label fluorophores and some of them require expensive labeling procedures. Furthermore, some of them are signal-off sensors, which can be troubled by false positives.

Biological thiols such as cysteine (Cys), homocysteine (Hcy), and glutathione (GSH) play essential roles in human physiology. Abnormal levels of biothiols are connected with many diseases. It’s of great interest to develop efficient methods for detection and quantification of biothiols. Up to date, lots of strategies such as liquid chromatography, capillary electrophoresis, voltammetry and flow injection, have been designed to detect biothiols. However, these methods generally require expensive instrument and tedious preparation protocols that limit the scope of their application. In the past few years, optical assays based on synthetic colorimetric and fluorescent probes have received increasing attention due to the simplicity, sensitivity and efficiency.

In this paper, we propose a turn on and label-free fluorescent probe for Hg$^{2+}$ with high sensitivity and selectivity. The simple sensing platform for Hg$^{2+}$ detection is based on a T-rich ss-DNA and the fluorescence resonance energy transfer (FRET) between graphene oxide (GO) and the Ruthenium complex, [Ru(bpy)$_2$(pip)]$^{2+}$ (Probe 1: T-rich ss-DNA, GO and [Ru(bpy)$_2$(pip)]$^{2+}$, P1) (Fig. 1). Initially, [Ru(bpy)$_2$(pip)]$^{2+}$ shows strong fluorescence in Tris-HCl buffer (pH = 7.0) at room temperature. [Ru(bpy)$_2$(pip)]$^{2+}$ can be adsorbed on the surface of GO to form a charge-transfer complex (GO-Ru) via π–π interactions and electrostatic interactions, and fluorescence of [Ru(bpy)$_2$(pip)]$^{2+}$ can thus be quenched by GO. The GO surface can also adsorb another component, i.e., T-rich ss-DNA, via π–π stacking, whenever T-rich ss-DNA is introduced into the probe system. In the presence of Hg$^{2+}$ in solution, T-rich ss-DNA will coordinate with Hg$^{2+}$ through thymine base (T) due to its higher affinity to Hg$^{2+}$, be detached from the GO surface. Two T-rich ss-DNAs will be coupled via T-Hg$^{2+}$–T base pairs to give ds-DNA. Subsequently, [Ru(bpy)$_2$(pip)]$^{2+}$ can be removed from the GO surface, and intercalates into...
the newly formed ds-DNA, resulting in the restoration of fluorescence. Accordingly, the restoration in fluorescent intensity of \([\text{Ru(bpy)}_2(pip)]^{2+}\) directly correlate to the amount of detection target (Hg\(^{2+}\)) in solution.

On the other hand, the S-donor atoms originated from biothiols exhibits higher affinity to Hg\(^{2+}\). Hence, upon addition of biothiols into the above GO-Ru- DNA/Hg\(^{2+}\) system, Hg\(^{2+}\) can be released from ds-DNA coupled by T-Hg\(^{2+}\)-T base pairs, and ds-DNA unwind to give ss-DNA. Then ss-DNA and \([\text{Ru(bpy)}_2(pip)]^{2+}\) can be adsorbed on the surface of GO, and the fluorescence of \([\text{Ru(bpy)}_2(pip)]^{2+}\) is quenched again. (Probe 2: GO, T-rich DNA, \([\text{Ru(bpy)}_2(pip)]^{2+}\) and Hg\(^{2+}\), P2) (Fig. 1). Herein, a highly selective fluorescence method for the detection of biothiols based on T-rich DNA, \([\text{Ru(bpy)}_2(pip)]^{2+}\), Hg\(^{2+}\) and GO has thus been introduced.

**Results**

GO was synthesized from graphite powder based on the Hummer’s method\(^4\). The TEM images of GO (a) and GO-Ru hybrid (b) were given in Fig. S2. It was noted that the GO surface was rough with a significant number of wrinkles. However, the surface of GO-Ru hybrid became more smooth, due to homogeneous adsorption of \([\text{Ru(bpy)}_2(pip)]^{2+}\) on the surface of GO. The UV/Vis spectra of \([\text{Ru(bpy)}_2(pip)]^{2+}\), GO and GO-Ru hybrid were shown in Fig. S3. The absorption peaks of both Ru-complex and GO were slightly broadened and red shifted (\(\Delta\lambda = 3 \sim 10\) nm), during the binding process of \([\text{Ru(bpy)}_2(pip)]^{2+}\) on GO surface to give GO-Ru hybrid. This is indicative of strong \(\pi-\pi\) stacking, hydrogen bonding and electrostatic interactions between GO and Ru-complex. Furthermore, the Raman spectra (Fig. S4) and FTIR spectra (Fig. S5) also provided direct evidences for the interaction between Ru complex and GO, and all these data were in good agreement with literatures\(^26\sim27\).

The fluorescence intensity of \([\text{Ru(bpy)}_2(pip)]^{2+}\) (2.0 \(\mu\)M) decreased rapidly when GO was added into the solution (Fig. S6 A). The fluorescence of the \([\text{Ru(bpy)}_2(pip)]^{2+}\) was quenched almost completely by GO, due to the strong interaction between \([\text{Ru(bpy)}_2(pip)]^{2+}\) and GO, and the quenching efficiency was estimated to be 85% when the concentration of GO was 5.0 \(\mu\)g/mL. Hence, in this paper, \([\text{Ru(bpy)}_2(pip)]^{2+}\) was accordingly used as the signal-reporter, and its final concentrations were kept to be 2.0 \(\mu\)M, while a final concentration of GO as the quencher was 5.0 \(\mu\)g/mL. It was noticed that the quenching efficiency of GO became a little lower, with the presence of T-rich ss-DNA in \([\text{Ru(bpy)}_2(pip)]^{2+}\) solution (Fig. S6 B), indicating a slight interaction between \([\text{Ru(bpy)}_2(pip)]^{2+}\) and T-rich ss-DNA, although this interaction was much weaker than that between \([\text{Ru(bpy)}_2(pip)]^{2+}\) and GO. Certainly this interaction may have impact on the detection, however, it can be deducted by background calibration.

For a successful design of Hg\(^{2+}\) assay, an optimal selection of T-rich ss-DNA is pivotal. In this work, three oligonucleotides, with different base sequence and length (from short to longer), were firstly selected and tested. They are: T\(_{10}\) (5’-GGGT TTTT TCCC-3’), T\(_{21}\) (5’-TTTT TTTT TTTT TTTT TTTT T-3’), and T\(_{30}\) (5’-TTTT TTTT TTTT TTTT TTTT TT -3’). As illustrated in Fig. 2, with the addition of Hg\(^{2+}\) into solution, T\(_{30}\) showed the highest fluorescence restoration, while T\(_{10}\) showed the lowest fluorescence restoration. On the other hand, it was interestingly noticed that T\(_{10}\) showed a better sensitivity for Hg\(^{2+}\), as demonstrated in Fig. S7 and Fig. S8. In addition to the length of the ss-DNA, a possible factor to account for the sensitivity could be the different affinities of nucleobases towards Hg\(^{2+}\), the relative binding energy was reported.
to be in the series G > A > C > T in aqueous medium. Therefore, as a compromise for efficiency, selectivity, even as well as cost, T21 was finally selected by us for constructing fluorescent probe for Hg.

To clarify the different interactions that may exist within the detection system, a systematic investigation was carried out, as shown in Fig. S9. The fluorescence intensity of [Ru(bpy)2(pip)]2+ had no obvious change, in the presence of Hg2+ ions, indicating no obvious interaction existed between [Ru(bpy)2(pip)]2+ and Hg2+. The fluorescence intensity of [Ru(bpy)2(pip)]2+ increased only about 42%, when [Ru(bpy)2(pip)]2+ mixed with T-rich ss-DNA (T21), indicating a weak interaction existed between [Ru(bpy)2(pip)]2+ and T21. However, the fluorescence intensity of [Ru(bpy)2(pip)]2+ increased up to 152%, if both Hg2+ ions and T-rich ss-DNA (T21) were present in the system. In this case, Hg2+ coordinated with the thymine on T21, and the single-strand DNA (T21) was coupled through T-Hg2+-T coordination bonds to give double-strand DNA. Then, [Ru(bpy)2(pip)]2+ could intercalate between the T-Hg2+-T ds-DNA base pairs, resulting in a transfer of the ruthenium complex [Ru(bpy)2(pip)]2+ from dark state to bright state.

The response curve of the turn-on sensor for Hg2+ is displayed in Fig. 3A. A linear relationship (R² = 0.99) (Fig. 3C) towards Hg2+ was calculated to be 2.34 nM, based on 3σ/slope (σ, standard deviation of the blank samples). The selectivity of the approach for Hg2+ is evaluated by comparing its response to Hg2+ and that to other metal ions (Ag+, Ba2+, Ca2+, Cd2+, Co2+, Cu2+, K+, Li+, Mg2+, Mn2+, Na+, Ni2+, Zn2+, Pb2+ and Sn2+). As shown in Fig. 3D, it was noticed that the fluorescent probe (P1) designed by us had excellent selectivity for Hg2+ (6.0 μM), over other metal ions even at a much higher concentration (10.0 μM). An anti-jamming capability testing for the fluorescent probe (P1) was also conducted. In Fig. S10, the results indicated again that the designed sensor had excellent anti-jamming capability and outstanding selectivity.

It is worth noting that the GO-Ru-T21 fluorescent probe (P1) can be expediently combined with mercury ion (Hg2+, at a constant concentration) to give another sensor system, GO-Ru-T21/Hg2+ fluorescent probe (P2) to detect biothiols. Interestingly it brings another important application for us, based on a competition mechanism previously described. Cysteine (Cys) or Glutathione (GSH) can effectively sequester Hg2+ by the formation of the strong S-Hg2+ bond. Therefore, this probe can be functioned as a fluorescence switch-off probe for biothiols such as Cys and GSH.

**Figure 3** | (A) Fluorescence spectra of the GO-Ru-T21 system (P1) (GO = 5.0 μg/mL, Ru = 2.0 μM, T21 = 3.0 μM) at different concentrations of Hg2+ (from bottom to top: 0, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, 8.0, 9.0, and 10.0 μM (the bottom black line was the fluorescence spectrum of GO-Ru complex)) in 10 mM Tris-HCl buffer (pH = 7.0) at room temperature. (B) Fluorescence intensity of P1 against the concentrations of Hg2+. (C) The linear relationship of the fluorescence intensity of the P1 against the concentrations (0–6 μM) of Hg2+. (D) Selectivity of the fluorescent probe to Hg2+ against different metal ions. The concentration of Hg2+ was 6.0 μM while the other metal ions were 10.0 μM. The excitation and emission wavelengths were 455 nm and 605 nm, respectively.
To maximize the efficiency of the detection system, we firstly incubated the T21 with Hg\(^{2+}\) for 30 mins to ensure the full formation of the T-Hg\(^{2+}\)-T ds-DNA, then GO-Ru hybrid was added and incubated for 30 mins again, prior to addition of Cys. With Cys concentration increasing, a gradual decrease in the fluorescence intensity at 605 nm was observed, with a linear relationship (R\(^2\) = 0.99) in the range from 0.0–5.0 \(\mu\)M, as shown in Fig. 4A, B and C. The limit of detection for Cys was calculated to be 6.20 nM (based on 3 s/slope).

Furthermore, the GO-Ru-T21/Hg\(^{2+}\) sensor system (P2) could also be applied to the detection of GSH under the same experimental conditions. With GSH concentration increasing, a gradual decrease in the fluorescence intensity at 605 nm was observed, with a linear relationship (R\(^2\) = 0.99) in the range from 0.0–5.0 \(\mu\)M, as shown in Fig. 4A, B and C. The limit of detection for Cys was calculated to be 6.20 nM (based on 3 s/slope).

To clarify the response mechanism of the sensor system, we carried out an experiment, to test whether the fluorescence change was caused by the direct interaction of Cys/GSH with [Ru(bpy)\(_2\)(pip)]\(^{2+}\). The result was given Fig. S13. It was found that the fluorescence intensity did not change if Cys or GSH was added into 2.0 \(\mu\)M [Ru(bpy)\(_2\)(pip)]\(^{2+}\) solution, even the concentration of Cys or GSH became as high as 20 \(\mu\)M. This result ruled out the possibility that the fluorescence response resulted from the direct interaction between Cys/GSH and [Ru(bpy)\(_2\)(pip)]\(^{2+}\). Therefore, the fluorescence decrease of the sensor system really depended on the removal of Hg\(^{2+}\) from T-Hg\(^{2+}\)-T ds-DNA, by the coordination of Cys or GSH with Hg\(^{2+}\).

To investigate the detection platform’s selectivity for biothiols, the fluorescence responses to the other common amino acids (Ala, Asn, Asp, Arg, Gin, Glu, Gly, His, Ile, Leu, Lys, Met, Phe, Pro, Ser, Thr, Trp, Tyr, Val) were also recorded, at the amino acid concentration of 100 \(\mu\)M, 10 times higher than the detecting target - biothiol. In Fig. 4D, it was clearly observed that no significant fluorescence decrease appeared with the addition of other common amino acids, except for Cys and/or GSH. An anti-jamming capability testing for the fluorescent probe (P2) was also carried out. In Fig. S14, the results indicated that the designed sensor had excellent selectivity, as well as a satisfied anti-jamming capability for detection of Cys/GSH against other common amino acids.

**Figure 4 |** (A) Fluorescence spectra of the GO-Ru-T21/Hg\(^{2+}\) system (P2) (GO = 5.0 \(\mu\)g/mL, Ru = 2.0 \(\mu\)M, T21 = 3.0 \(\mu\)M, [Hg\(^{2+}\)] = 9.0 \(\mu\)M) in the presence of increasing concentrations of Cys (0, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, 10.0, 12.0 and 14.0 \(\mu\)M). (B) Fluorescence intensity of P2 against the concentrations of Cys. (C) The linear relationship of the fluorescence intensity of the P2 against the concentrations (0–5 \(\mu\)M) of Cys. (D) Selectivity of the fluorescent probe to Cys/GSH against different amino acids. The relative fluorescence intensity of fluorescent probe in the presence 10 \(\mu\)M Cys, GSH, GSSG and 100 \(\mu\)M other various amino acids. The excitation and emission wavelengths were 455 nm and 605 nm, respectively.
### Discussion
Graphene oxide (GO), with aromatic domains and carboxyl groups, is a remarkable nanomaterial for sensing applications. The interesting and important example is that GO can differentiate various DNA structures such as ss-DNA, ds-DNA and stem-loops. Even though both ss-DNA and GO are negatively charged, ss-DNA can still be adsorbed on the surface of GO in buffers containing a high concentration of salt to screen electrostatic repulsion. The attractive forces between DNA and GO include π−π stacking, hydrophobic interaction, hydrogen bonding, and van der Waals forces. Compared to ss-DNA, the affinity between ds-DNA/quadraplexes and GO is much weaker. Adsorbed ss-DNA can be desorbed by adding its complementary DNA (cDNA) or some other targets to form a duplex/G-quadraplexes. On the other hand, GO can be used as a good quencher, since fluorophores adsorbed on GO are effectively quenched by electron transfer or energy transfer. These interesting properties of GO have been exploited to develop a highly sensitive fluorescent sensor.

[Ru(bpy)2(pip)]2+ (bpy = 2,2’-bipyridine; pip = 2-phenylimidazo[4,5-f][1,10]phenanthroline) has prominent DNA-binding charge, [Ru(bpy)2(pip)]2+ could interact with GO by π−π interactions, hydrogen bonding and electrostatic interactions. The tapping mode AFM image of the GO indicated that the average thickness of GO sheets is ~1.1 nm (Fig. S1, above), and the average size of GO is above 500 nm (Fig. S1). However, the mean thickness of Ru-GO hybrid was determined to be ~1.4 nm (Fig. S1, below). The significant increase in thickness of Ru-GO hybrid probably resulted from the covering of [Ru(bpy)2(pip)]2+ molecules on the surface of GO sheet via π−π interactions. This data might provide a direct proof that [Ru(bpy)2(pip)]2+ could be adsorbed on the surface of GO.

In summary, in this paper, we have successfully integrated the versatile functions of Graphene oxide (GO), with the distinct features of ruthenium complex [Ru(bpy)2(pip)]2+ and T-rich ss-DNA, to develop a label-free, selective detection strategy for Hg2+ and biothiols. The turn-on fluorescent sensor for Hg2+ is based on the competitive binding of [Ru(bpy)2(pip)]2+ with GO, or with ds-DNA. The ds-DNA is only given with the presence of Hg2+, by coupling T-rich ss-DNA via T–Hg2+-T base pairs. Thus this turn-on step can be applied to sensing mercury ion. Subsequently, this sensor system can also be utilized to detect biothiols (Cys or GSH). The higher affinity of the sulfur atoms of biothiols to Hg2+ can induce ds-DNA formed by T-Hg2+-T based pair unwinding to give ss-DNA. Then [Ru(bpy)2(pip)]2+ is released from ds-DNA, and adsorbed again on the surface of GO, leading to the quenching of [Ru(bpy)2(pip)]2+ fluorescence. The assay exhibited high selectivity and sensitivity, with the limits of detection for Hg2+, cysteine (Cys) and glutathione (GSH) to be 2.34 nM, 6.20 nM and 4.60 nM, respectively. We expect that this strategy may offer a new approach for developing low cost and sensitive sensors in biological and environmental applications.

### Methods
**Preparation of GO.** GO was synthesized from graphite powder based on the Hummer’s method. Graphite powder of spectrographic grade was purchased from Sinopharm Chemical Reagent Co. Ltd. (China).

**Synthesis of [Ru(bpy)2(pip)]2+.** [Ru(bpy)2(pip)]2+ was synthesized by the literature routes.

**Preparation of GO-Ru hybrid.** 5.0 mL GO solution (100.0 µg/mL) and 1.0 mL Ru(bpy)2(pip)]2+ solution (200.0 µM) were mixed in a 15.0 mL plastic centrifuge tube, and diluted with 4.0 mL ultrapure water. Then the solution was sonicated at 20°C for 20 minutes in order to fully mixed and dispersed, to go GO-Ru hybrid. The final concentrations of [Ru(bpy)2(pip)]2+ and GO were 20.0 µM and 50.0 µg/mL, respectively.

**Preparation of DNA.** Three purified T-rich oligonucleotides (T10 (5’-GGGT-TTTT-TTTT-TCC-3’); T21 (5’-TTTT-TTTT-TTTT-TTTT-TTT-3’); T30 (5’-TTTT-TTTT-TTTT-TTTT-TTTT-3’)) were obtained from Sangon Biotech Co., Ltd (Shanghai, China). The stock solutions of oligonucleotides were prepared in 10 mM Tris-HCl buffer (pH = 7.0). The DNA solutions were heated at 90°C for 6 minutes to dissociate any intermolecular interaction, and gradually cooled to room temperature (25°C). Then, the DNA solutions were stored at 4°C before use. The stock solutions were diluted by Tris-HCl buffer (10 mM, pH 7.0) to the required concentration prior to use. Lambda Bio 40 UV–vis Spectrophotometer (Perkin-Elmer, USA) was used to quantify the oligonucleotides, with the extinction coefficients (ε/M·cm–1) at 260 nm for each nucleotide: G = 11500, C = 7400, T = 8700.

**Fluorescence response curve of Hg2+.** T10 (final concentration: 3.0 µM) and different amount of Hg2+ (final concentration: 0, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, 8.0, 9.0, and 10.0 µM, respectively) was mixed and diluted with buffer (10 mM Tris-HCl buffer, pH = 7.0) to a final volume of 900 µL in a 1.5 mL plastic centrifuge tube, and incubated for 30 minutes to ensure full formation of the T-Hg2+·T ds-DNA. Then 100 µL GO-Ru hybrid was added and incubated for another 30 minutes. The fluorescence spectra were recorded at room temperature on an F-7000 fluorescence spectrophotometer (Hitachi) with a quartz cell (1 cm). The excitation and emission wavelengths were 455 nm and 605 nm, respectively. Both excitation slit width and emission slit width were 10 nm.

**Fluorescence response curve of Cys/GSH.** T10 (final concentration: 3.0 µM) and Hg2+ (final concentration: 9.0 µM) was mixed and diluted with buffer (10 mM Tris-HCl buffer, pH = 7.0) to a final volume of 800 µL in a 1.5 mL plastic centrifuge tube, and incubated for 30 minutes to ensure full formation of the T-Hg2+·T ds-DNA. Then 100 µL GO-Ru hybrid was added and incubated for 30 minutes. Next, different amount of Cys or GSH was added to the solution to the final concentration of 0, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, 10.0, 12.0 and 14.0 µM, respectively, and diluted with buffer (10 mM Tris-HCl buffer, pH = 7.0) to a final volume of 1.0 mL, incubated again for 10 minutes. The fluorescence spectra were recorded at room temperature on an F-7000 fluorescence spectrophotometer (Hitachi) with a quartz cell (1 cm). The excitation and emission wavelengths were 455 nm and 605 nm, respectively. Both excitation slit width and emission slit width were 10 nm.
