Case Report

Childhood giant omental and mesenteric lipoma

\textbf{A B S T R A C T}

Omental and mesenteric lipomas are very rare benign lesions of mature adipose tissue. They are well-defined, noninvasive, and encapsulated masses that can be discovered in asymptomatic patients or may cause variable nonspecific symptoms depending on their size and location. The omental and mesenteric lipoma has confusing features in ultrasound; however, computed tomography and magnetic resonance imaging can well characterize and demarcate these lesions. Though few cases of mesenteric and omental lipomas have been reported in the literature, but because of its large size and childhood presentation, the case we present, can be one of the largest childhood omental and mesenteric lipomas ever reported. A 6-year-old girl presented with slowly progressing abdominal distension and repeated dull abdominal pain for last 4 years. Abdominal and pelvic computed tomography examination revealed a huge mesenteric and omental lipoma that was resected surgically without any complications.

\textbf{Case report}

A six-year-old girl presented with slowly progressing abdominal distension and repeated dull abdominal pain for last 4 years. No history of vomiting, diarrhea, constipation, or urinary tract symptoms were present.

Abdominal ultrasound examination revealed a large, heterogeneous, relatively echogenic mass lesion occupying almost entire abdominal cavity. The outlines of the lesion were not well recognizable on ultrasound. Apart from displacement of the major abdominal viscera to periphery of the abdominal cavity, no gross abnormality was detected in the intra-abdominal organs.

The patient subsequently underwent the abdominal and the pelvic computed tomography (CT) examination with 128-slice Siemens scanner.

CT images revealed a huge, well-defined, low density, fat attenuation, nonenhancing, intraperitoneal, mass lesion occupying majority of the abdominal cavity. This large mass lesion was extending from just beneath the right dome of diaphragm down to level of symphysis pubis. Multiple fibrous septations and few specks of calcifications were seen within this essentially fatty lesion. No major abdominal vessels were traversing the lesion. There was no evidence of inflammatory reaction or infiltration of surrounding structures or tissues (Fig. 1A).

This well demarcated huge mass lesion was compressing the bowel loops rather than infiltrating them; however, no extension of the mass lesion was seen to the retroperitoneal spaces.

There was no sign of entering of any part of this fatty lesion into the spaces between the liver and right kidney or spleen and left kidney. This finding excluded the possibility of peritoneal lipomatosis.

The retroperitoneal structures and the bowel loops were displaced posterolaterally toward the abdominal walls. There was no evidence of any obstructive compression on gastrointestinal or urinary tract organs (Fig. 1B).

This mass lesion measured 28 × 24 × 10 cm³ in maximum craniocaudal, transverse, and anterioposterior dimensions, respectively.

The patient underwent open abdominal surgery under general anesthesia and a huge, encapsulated mass was discovered adherent to the stomach, transverse colon, intestinal mesentery, and posterior abdominal wall. The mass was not separable from both the omentum and the mesentery.

As the mass lesion was neither originating form nor infiltrating the important abdominal viscera and blood vessels, so this huge; 4 kilograms mass lesion was easily resected without major bleeding or postoperative complications.

Macroscopically it was a large, tan and gray color glistening surfaced, encapsulated, moderately firm mass. The cut sections of the mass showed homogenous yellowish tan soft surfaces (Fig. 2).

Microscopic sections showed tumor composed of large nodules and a sheet of mature adipocytes without atypia that were separated by thin fibrous bands. The findings were negative for malignancy (Fig. 3).

Keeping in view the clinical, radiological, surgical, and histological findings; a rare childhood giant omental and mesenteric lipoma was diagnosed.

Discussion

Lipomas are benign, well-defined, noninvasive, and encapsulated tumor of mature adipose tissue [1]. These common benign lesions can arise in any part of the body [2], but mesenteric and omental lipomas are rare entities [3,4].

A literature review performed by Cha, Jae Myung et al at 2007 showed that less than 30 cases of mesenteric lipomas were reported with only 7 cases in children. He presented a lipoma of 19 × 10 × 5.1 cm³ in a 29-year-old man and argued that this was one of the largest lipomas reported in literature [3]. The case presented here; can exactly be one of the largest childhood omental and mesenteric lipomas reported.

Mesenteric lipomas are slow-growing, mobile, soft, masses that does not infiltrate the surrounding organs [5,6].

Abdominal cavity lipomas may be discovered as asymptomatic masses or they may cause variable nonspecific symptoms. These symptoms include progressive abdominal swelling, abdominal pain, and bowel obstruction. The diagnosis of lipoma is often made incidentally on imaging studies. The imaging findings of lipoma are characteristic and include a well-defined, low-attenuation mass lesion without contrast enhancement. The mass lesion is usually homogeneous and typically found in the retroperitoneal space.

Macroscopically, the lipoma appears as a well-circumscribed, yellow to white mass. Microscopically, the tumor is composed of mature adipocytes with no evidence of cellular atypia or mitotic activity. Lipomas are benign lesions and have a low risk of recurrence after surgical excision.

Fig. 1 – (A) Contrast-enhanced right parasagittal CT section through the abdomen and pelvis shows a huge, well-defined, low density, nonenhancing, intraperitoneal, mass lesion extending from the diaphragm down to pelvis. Note the fibrous septa and a calcified focus (arrow). No evidence of inflammatory reaction or infiltration of surrounding structures. (B) Contrast-enhanced axial CT section through the abdomen and pelvis: The well demarcated, low attenuating mass lesion is compressing the bowel loops rather than infiltrating them (arrows). No extension to the retroperitoneal spaces. The retroperitoneal structures and the bowel loops are displaced posterolaterally (arrows). No evidence of any obstructive compression on gastrointestinal or urinary tract organs.
When the omental and mesenteric lipomas are large enough, they can be palpated as soft to firm masses in physical examination [9].

**Imaging features**

Ultrasound can detect abdominal lipomas as homogenous echogenic masses; however, they may present a confusing picture from homogenous to heterogeneous echo pattern [3]. If not so large, abdominal lipomas can be misdiagnosed as normal mesenteric fat [3].

Thin fibrous septations [7] and calcification may be present in up to 11% of cases [10].

CT and magnetic resonance imaging can well depict these fatty tumors [9].

CT shows the typical fat tissue attenuation values [11] from (−80 to −120 HU) [12,13]. CT can also determine the omental or mesenteric origin of the tumor and depicts the precise anatomic features [14].

Magnetic resonance imaging, owing the high capability of tissue characterization, can nicely differentiate the lesion from adjacent structures and depict precise anatomic demarcations.

Lipoma will demonstrate homogeneous signal intensity identical to fat in all pulse sequences. The thin fibrous septa will show low signal intensity on T1- and T2-weighted images [12].

Because of lack of published reports, the long-term behavior of these lesions is not well known in children [15]; therefore, a long-term follow-up is advised [7].
