Detecting a true quantum pump effect

Colin Benjamin

Centre de Physique Theorique, CNRS.UMR 6207-Case 907, Faculte des Sciences de Luminy, 13288 Marseille Cedex 09, France.

Abstract. Even though quantum pumping is a very promising field, it has unfortunately not been unambiguously experimentally detected. The reason being that in the experiments the rectification effect overshadows the pumped current. One of the better known ways to detect it is by using the magnetic field symmetry properties of the rectified and pumped currents. The rectified currents are symmetric with respect to magnetic field reversal while the pumped currents do not possess any definite symmetry with respect to field reversal. This feature has been exploited in some recent works. In this work we look beyond this magnetic field symmetry properties and provide examples wherein the nature or magnitudes of the pumped and rectified currents are exactly opposite enabling an effective distinction between the two.

PACS. 73.23.Ra – 72.10.Bg

1 Introduction

Quantum pumping is an unique way to transport charge or spin without applying any voltage bias[1,2]. The idea of quantum pumping has been around for a long time beginning with the works of Thouless in Ref. [3] and Niu in Ref. [4] and later with the works of Buttiker, Thomas and Pretre in Ref. [5], Brouwer in Ref. [6] and Zhou, Spivak and Altshuler in Ref. [8]. Regrettably the unambiguous detection of this effect has not been possible till date[10]. The experiment [11] which was originally thought to be a quantum pumping experiment is now universally accepted as a detection of rectified currents[12]. Although there might have been a pumped current which unfortunately was masked by the rectified currents[9,10,13]. Experimentally, what seems to happen in pumping experiments is that the time dependent parameters may through stray capacitances directly link up with the reservoirs and thus indirectly induce a bias which is the origin of the rectified current[10]. The reason why the urgent detection of a true quantum pump effect is immediately required is that the time dependent parameters may through stray capacitances directly link up with the reservoirs and thus indirectly induce a bias which is the origin of the rectified current[10].

The essential difference between the rectified currents and the pumped currents is that the time dependent parameters may through stray capacitances directly link up with the reservoirs and thus indirectly induce a bias which is the origin of the rectified current[10].

In a two terminal setup is given by [10]:

\[ I_{\text{rect}} = \frac{w}{2\pi} R \int_S dX_1 dX_2 (C_1 \frac{\partial G}{\partial X_1} - C_2 \frac{\partial G}{\partial X_2}) \] (1)

\[ I_{\text{pump}} = \frac{e}{\pi} \int_A dX_1 dX_2 \sum_{\beta} \sum_{\alpha \in 1} \text{Im} \left( \frac{\partial S_{\alpha \beta}^*}{\partial X_1} \frac{\partial S_{\alpha \beta}}{\partial X_2} \right) \] (2)

In the above equation, \( S_{\alpha \beta} \) defines the scattering amplitude (reflection/transmission) of the mesoscopic sample, the periodic variation of the parameters \( X_1 \) and \( X_2 \) follows a closed path in a parameter space and the pumped current depends on the enclosed area \( A \) in \( (X_1,X_2) \) parameter space. Initially, the mesoscopic sample is at equilibrium and for it to transport current one needs to simultaneously vary two system parameters \( X_1(t) = X_1 + \delta X_1 \sin(\omega t) \) and \( X_2(t) = X_2 + \delta X_2 \sin(\omega t + \phi) \), herein \( \delta X_1 \) defines the amplitude of oscillation of the adiabatically modulated parameters. In the adiabatic quantum pumping regime we consider the system thus is close to equilibrium[7].

The essential difference between the rectified currents and the pumped currents are while the former is bound to be symmetric with respect to magnetic field reversal (via, Onsager’s symmetry) since the conductance[13] and it’s derivatives enter the formula, the pumped currents...
would have no definite symmetry with respect to magnetic field reversal \cite{17,18} since they in turn depend on the complex scattering amplitudes which have no specific dependence on field reversal unless the scattering system possesses some specific discrete symmetries \cite{18}. The main motivation of this work is to provide examples beyond the distinctive properties the two currents possess with respect to magnetic field reversal.

The examples show that the currents can be easily differentiated, either there natures are so different or their magnitudes are so very different that it enables an easy detection. The three examples provided are: (1) pumped and rectified currents in presence of magnetic barriers, (2) pumped and rectified currents in a normal metal double barrier structure and finally (3) pumped and rectified currents at a normal metal-charge density wave interface. In example (1) while the pumped currents are cent percent spin polarized the rectified currents are completely unpolarized, in example (2) pumped current is finite while the rectified current is zero, and finally in example (3) the rectified current again is zero while pumped current is finite. Of course these examples are by no means the only examples that can be found there might be numerous other examples wherein the pumped and rectified currents vary in such a distinct fashion apart from of-course the distinction brought out by magnetic field symmetry. In Ref. \cite{20} the authors consider a three terminal structure with a single normal metal lead with two superconducting leads. The pumped current into the normal metal lead has no definite symmetry with respect to the phase of the order parameter while the conductance is symmetric in phase. In another interesting work \cite{21}, the effect of dephasing was considered and it was shown that effect of dephasing on rectification effects is less pronounced than for quantum pumping.

The rectified currents in the adiabatic quantum pumping regime we consider differ from that in the non-linear dc bias regime. In the latter the Onsager symmetry relations are not obeyed \cite{22} while in the former (from Eq. 1) they are obeyed. Further rectification can also be talked of when a high frequency electromagnetic field is applied to a phase coherent conductor \cite{22}. This case also falls into the non-linear regime.

Our motivation in this work is plain. We provide three examples wherein the distinctive characteristics of the pumped and rectified currents are brought out. The symmetry properties these currents have with respect to magnetic field reversal are not as clear cut as it would seem initially. For example in Ref. \cite{18} it was pointed out that if the mesoscopic scatterer has some distinct spatial symmetries then the pumped current itself can be symmetric with respect to magnetic field reversal. Our work hopefully will provide a compass which would point into clear blue water between rectified and pumped currents.

\section{Examples}

In the examples below we look into the weak pumping regime for both the rectified as well as the pumped currents, since we can derive analytical expressions in this regime. The weak pumping regime is defined as one wherein the amplitude of modulation of the parameters is small, i.e., \( \delta X_i \ll X_i \). In the weak pumping regime the rectified current reduces to:

\[ I_{\text{rect}} = I_{\text{rect}}^0 \left[ C_1 \frac{\partial T}{\partial X_1} - C_2 \frac{\partial T}{\partial X_2} \right] \]  

with \( I_{\text{rect}}^0 = \frac{we^2}{8\pi^2} \sin(\phi) \delta X_1 \delta X_2 R/4\pi^2 \hbar \). \( T \) is the transmission coefficient of the mesoscopic scatterer, and for the special case of capacitances with equal magnitude, i.e., \( C_1 = C_2 = C \) one has:

\[ I_{\text{rect}} = I_{\text{rect}}^0 \left[ \frac{\partial T}{\partial X_1} - \frac{\partial T}{\partial X_2} \right] \]  

with \( I_{\text{rect}}^0 = \frac{we^2}{8\pi^2} \sin(\phi) \delta X_1 \delta X_2 RC/4\pi^2 \hbar \). Similarly the pumped current into lead \( \alpha \) are:

\[ I_{\text{pump},\alpha} = I_{\text{pump}}^0 \sum_{\beta} \sum_{\gamma \in \{1\}} |r_{\alpha \beta}^\gamma| \text{Im} \left( \frac{\partial S_{\alpha \beta}^\gamma}{\partial X_1} \frac{\partial S_{\alpha \beta}^\gamma}{\partial X_2} \right) \]  

with \( I_{\text{pump}}^0 = \frac{we}{2\pi} \sin(\phi) \delta X_1 \delta X_2 /2\pi, w \) is the frequency of the applied time dependent parameter, \( \phi \) is the phase difference between the parameters and \( e \) is the electronic charge.

\subsection{Magnetic barrier’s}

The first example is of pumping and rectification in case of a magnetic barriers. The model of our proposed device is exhibited in Fig. 1. It is essentially a 2DEG in the \( xy \) plane with a magnetic field in the \( z \)-direction. The magnetic field profile we consider is of delta function type for simplicity, \( B = B_0(x) \hat{z} \) with \( B_0(x) = B_0[\delta(x + d/2) - \delta(x - d/2)] \), wherein \( B_0 \) gives the strength of the magnetic field and \( d \) is the separation between the two \( \delta \) functions (see Fig.1(c)). The above form of the magnetic field is an approximation of the more general form seen when parallelly magnetized ferromagnetic materials are lithographically patterned on a 2DEG (Fig.1(b)). This approximation is not novel to this work but has been used in a number of works, see Ref. \cite{21} for further details. Magnetic barrier’s can not only be formed by this method but also when a conduction stripe with current driven through it is deposited on a 2DEG, and also when a super-conductor plate is deposited on a 2DEG, see Refs. \cite{23,24,25} for details. The structure depicted in Figure 1 has been experimentally produced as shown in Ref. \cite{24}. There are a host of experiments \cite{26} wherein such type of and similar structures are made, discussed and transport measurements carried out.

A 2DEG in the \( xy \) plane with a magnetic field pointing in the \( z \) direction is described by the Hamiltonian:

\[ H = \frac{1}{2m^*} \left[ p_x^2 + eA(x)^2 + \frac{e^2}{2m_0} \frac{\sigma \hbar}{2} B_z(x) \right] + \frac{1}{2m^*} \left[ p_y^2 + \left[ p_y + eA(x)^2 \right]^2 \right] + \frac{e^2}{2m_0} \frac{\sigma \hbar}{2} B_z(x) \]  

\[ + \frac{1}{2m^*} \left[ p_x^2 + eA(x)^2 + \frac{e^2}{2m_0} \frac{\sigma \hbar}{2} B_z(x) \right] + \frac{1}{2} \left[ p_y^2 + \left[ p_y + eA(x)^2 \right]^2 \right] + \frac{e^2}{2m_0} \frac{\sigma \hbar}{2} B_z(x) \]
The magnetic vector potential is zero otherwise. The last tron cyclotron frequency for simplicity we introduce dimensionless units, the electronic length in the landau gauge for the region A for electrons incoming from the right by A, and for incoming electrons from the left by A, and for electrons incoming from the right by A(x) = −B0y. The magnetic vector potential is zero otherwise. The last term in Eq. 6 is zero everywhere except at x = ±d/2. For simplicity we introduce dimensionless units, the electron cyclotron frequency \( \omega_c = eB_0/m^*c \), and the magnetic length \( l_B = \sqrt{\hbar c/eB_0} \), with \( B_0 \) being some typical magnetic field. All the quantities are expressed in dimensionless units: the magnetic field \( B_z(x) \rightarrow B_0B_z(x) \), the magnetic vector potential \( \mathbf{A}(x) \rightarrow B_0\mathbf{A}(x) \), the coordinate \( x \rightarrow x/l_B \) and the energy \( E \rightarrow (\epsilon_0E)(=E_0/E) \).

Since the Hamiltonian as depicted in Eq. 6 is translationally invariant along the y-direction, the total wave-function can be written as \( \Psi(x, y) = e^{i\psi(x)}q(x) \), wherein q is the wave-vector component in the y-direction. Thus one obtains the effective one-dimensional Schroedinger equation:

\[
\frac{d^2}{dx^2} - \{ A(x) + q \}^2 - \frac{eg^*}{2m_0} \sigma m^* \hbar B_z(x) + \frac{m^*}{\hbar^2} E|\psi(x)| = 0
\]

(7)

The S-matrix for electron transport across the device can be readily found out by matching the wave functions and as there are \( \delta \) function potentials there is a discontinuity in the first derivative. The wave functions on the left and right are given by \( \psi_1 = (e^{ik_1x} + re^{-ik_1x}) \) and \( \psi_3 = te^{ik_1x} \), while that in the region \(-d/2 < x < d/2\) is \( \psi_3 = (ae^{ik_2x} + be^{-ik_2x}) \). The wave vectors are given by: \( k_1 = \sqrt{2E - q^2} \), \( k_2 = \sqrt{2E - (q + B_z)^2} \) and for electrons incident from the right, \( k_2 \) in the wave-functions is replaced by \( k_2' = \sqrt{2E - (q - B_z)^2} \). With this procedure outlined above one can determine all the coefficients of the S-Matrix

\[
S_\sigma = \begin{pmatrix} s_{\sigma 11} & s_{\sigma 12} \\ s_{\sigma 21} & s_{\sigma 22} \end{pmatrix} = \begin{pmatrix} r_\sigma & t_\sigma' \\ t_\sigma & r_\sigma' \end{pmatrix}
\]

\[
r_\sigma = -i\sin(k_2d)(k_1^2 - k_2^2 - \lambda^2 - 2i\lambda\sigma k_1)
\]

\[
t_\sigma = \frac{2k_1k_2}{D}, t'_\sigma = \frac{2k_1k_2'}{D'}
\]

\[
r'_\sigma = -i\sin(k_2'd)(k_1^2 - k_2'^2 - \lambda^2 + 2i\lambda\sigma k_1)
\]

\[
D = 2k_1k_2\cos(k_2d) - i\sin(k_2d)(k_1^2 + k_2^2 + \lambda^2),
\]

\[
D' = 2k_1k_2'\cos(k_2'd) - i\sin(k_2'd)(k_1^2 + k_2'^2 + \lambda^2),
\]

\[
\lambda = \frac{g^*B_z}{2}, k_1 = \sqrt{2E}, k_2 = \sqrt{2E - (q + B_z)^2}
\]

and \( k_2' = \sqrt{2E - (q - B_z)^2} \).

One can readily see from the transmission coefficients, there is no spin polarization as \( T_{z+} = T_{z-} \). This type of structure has already been studied in Ref.[14] where it’s remarkable pure pumped spin current properties were noticed. In this work we compare and contrast the pumped currents with the rectified currents and show that the rectified currents are completely unpolarized. This provides an unique way to distinguish the two effects. The schematic of the system is exhibited in Fig. 1. In the following consider \( q = 0 \), and therefore \( k_2' = k_2 \).

Initially, the device is in equilibrium, and for it to transport current one needs to simultaneously vary two system parameters \( X_1(t) = X_1 + \partial X_1\sin(\omega t) \) and \( X_2(t) = X_2 + \partial X_2\sin(\omega t + \phi) \), in our case \( X_1 \) is the width d and \( X_2 \) the magnetic field \( B_z \) given in terms of the magnetization strength \( B_0 = M_0h \), where \( h \) is the height and \( M_0 \) the magnetization of the ferromagnetic stripe. To invoke pumping in our proposed system we modulate the width \( d = d_0 + d_p\sin(\omega t) \) and magnetic field strength \( B_z = B_z + B_p\sin(\omega t + \phi) \). Herein \( w \) is the pumping frequency and \( \phi \) is the phase difference between the two modulated parameters. Thus in this adiabatic pumping regime the system is close to equilibrium. The transmission coefficient of this structure which in effect is the Landauer conductance is:

\[
T = \frac{4k_1^2k_2^2}{4k_1^2k_2^2\cos^2(k_2d) + (\lambda^2 + k_1^2 + k_2^2)^2\sin^2(k_2d)}
\]

with \( k_1 = \sqrt{2E}, k_2 = \sqrt{2E - B_z^2} \) and \( \lambda_1 = \frac{g^*B_z}{2} \).

As is self evident, the transmission is completely unpolarized, i.e. \( T_{z+} = T_{z-} \). This fact was discovered only in Ref.[27], two earlier works[28] had mistakenly attributed spin polarizability properties to the device (as depicted in Fig. 1) when a bias is applied. Further because of the fact that spin polarization is absent in presence of a bias, there wont be any spin accumulation[29] either. Hence from Eq. 4, since the rectified current involves the derivatives of
Fig. 2. (Color online) Energy dependence of the pumped current normalized by $I_{pump}^0$. Spin polarized pumping delivering a finite net spin current along-with zero charge current. The parameters are $B_x = 5.0, d_0 = 5.0, \phi = \pi/2, g^* = 0.44$ and wavevector $q = 0$. In the inset the rectified currents are plotted. The rectified currents normalized by $I_{rect}^0$ (for same parameters as for pumping) are of-course completely unpolarized.

The conductance with respect to the modulated parameters as in Eq. 4, $X_1 = B_z$ and $X_2 = d$, the rectified current is completely unpolarized. The explicit expression for the rectified and pumped currents are:

$$I_{rect} = I_{rect}^0 \frac{-\sin^2(k_2d)f' + k_2 \sin(2kd)(f-1)}{T_d^2},$$

with $f = \frac{\lambda_1^2 + k_1^2 + k_2^2}{2k_1 k_2}$,

$$f' = \frac{(2EB_z(4 + g^* B) + B_z^2(g^2 - 4)(1 - B_z))}{(64E(2E - B_z^2)^2)}$$

and $T_d = \cos^2(k_2d) + f \sin^2(k_2d)$.

In contrast the pumped currents as in Ref. [14], are given as:

$$I_\sigma = \sigma I_{pump}^0 \frac{2B_z^2g^*g'k_1^3k_2^3 \sin(2kd)}{T_d^2},$$

$$I_{sp} = I_{+1} - I_{-1} = I_{pump}^0 \frac{4B_z^2g^*g'k_1^3k_2^3 \sin(2kd)}{T_d^2},$$

$$I_{ch} = I_{+1} + I_{-1} = 0,$$

with $g' = 1 - \frac{g^*}{2}$,

$$T_d = 4k_1^3k_2^3 \cos^2(k_2d) + [4E - g'^2 B_z^2] \sin^2(k_2d),$$

$$I_{pump}^0 = \frac{weB_zd_0 \sin(\phi)}{2\pi},$$

and

$$I_{rect}^0 = we^2 \sin(\phi)B_p d_p RC / 4\pi^2 \hbar.$$

The rectified currents as is evident from the above equations are completely unpolarized, while the pumped currents are completely spin polarized. There is net zero pumped charge current while a finite pure spin current flows. In Fig. 2 we show the plots for the pumped currents with the rectified currents plotted in the inset of the figure. The figure for the rectified currents is for equivalent coupling of stray capacitances, but the unpolarized nature of the rectified current will be valid as well in case of non-equivalent stray capacitances, since the transmission is completely unpolarized. For $q \neq 0$, as before we have completely unpolarized rectified currents, but in the pumping regime we no longer have pure spin pumped polarized currents but both pumped finite spin and charge currents. Thus the system can again discriminate between pumped and rectified currents but not as effectively as for the $q = 0$ case.

To conclude the analysis of magnetic barriers, we have shown distinct properties of the rectified and pumped currents. The experimental realization of such type of structures has already been achieved. The only thing one has to add is to adiabatically modulate two independent parameters of our structure (to derive the currents above we have modulated the width of the magnetic barrier and it’s strength) to see the distinctive spin polarizability properties the currents possess. To do this one can make a point contact between the ferromagnetic stripe and the 2DEG interface applying an ac gate voltages to this point contact can change the shape of the structure while to change the strength of the barrier one can apply an external time dependent magnetic field to the ferromagnetic stripe.

2.2 Normal metal double barrier structure

![Fig. 3. The double barrier structure. The normal metal double barrier structure is defined via the potential: $V_1\delta(x) + V_2\delta(x - l)$.](image)

In these type of structures pumping has again been studied as in Ref. [31]. We consider two $\delta$ function potentials separated by a length $l$ as in Fig. 3. The transmission and reflection amplitudes for such type of structures can be easily calculated by matching the wave-functions at the three interfaces and then by taking into account the jump in the first derivative at the interfaces. The transmission coefficient for this structure is given as:

$$T = \frac{4}{a^2 + b^2},$$

with $a = z_1z_2 \sin(\delta l) + (z_1 + z_2) \cos(\delta l) - 2 \sin(\delta l)$, $b = 2 \cos(\delta l) + (z_1 + z_2) \sin(\delta l)$, and $z_i = \frac{\eta_i}{\hbar}.$

To invoke pumping in these structures we modulate the strengths of the barrier potentials, thus $z_1 = z_{01} + \ldots$. 

A
Here we show that the rectified currents are zero in contrast while pumped currents are finite. Of course this result is independent of whether or not \( C_1 = C_2 \). We consider a normal metal - charge density wave junction with an interface at \( x = 0 \) as in Fig. 5. In the charge density wave region \( (x > 0) \) the order parameter \( \Delta(x) = \Delta e^{i\chi} \) near the interface is not constant but decays smoothly over a finite length of the order of the coherence length \[31\]. This is the charge density wave proximity effect. In our analysis of the problem we disregard the proximity effect and assume a step function pair potential. The structure we work with is depicted in Fig. 5.

2.3 Normal metal- Charge density wave interface

Finally we show that pumping and rectification currents at a normal metal charge density wave interface can also be easily distinguished since the pumped currents are finite while rectified currents are again zero. Since the conductance is effectively zero this result is in fact independent of the strength of the stray capacitances as in Fig. 5. In Fig. 5 of whether or not

\[
\Delta \propto \delta(x)
\]

The experimental realization of this structure is not at all difficult, since double barrier structures have been experimentally realized for long. The only thing is by having two ac dependent gate voltages to modulate the shape of the double barrier structure such that the coupling to the stray capacitances may be equal. If this condition is realized then this very simple structure will be a very good identifier of a genuine quantum pump effect if present.

Of course not any structure with equivalent stray capacitances will give zero rectified current nor would any device with equi-potential barriers, the most important fact is the equality \( dT/dz_1 = dT/dz_2 \), which has to satisfied for the absence of rectified currents.

A delta function potential \( V\delta(x) \) at the interface models the impurity which pins the charge density wave. We also assume the charge density wave and normal metal to be one dimensional and average electron densities are equal. The fermi wave-number \( k_F \) and the effective masses are assumed to be equal in the normal metal and charge density wave regions. The scattering matrix of such a junction has been derived earlier in Ref. \[33\]. Here we give the results. The scattering amplitudes of the structure depicted in Fig. 5 are given below:

![Fig. 4.](image)

![Fig. 5.](image)
As is evident the transmission is zero in the tunnelling regime.

Fig. 6. (Color online) The transmission and reflection probabilities are plotted (parameters are mentioned in the figure). As is evident the transmission is zero in the tunnelling regime.

The unique thing of our structure where the macroscopic phase of the superconductor structure where the macroscopic phase of the charge density wave material for such a structure in the tunnelling regime.

In Fig. 7, we plot the pumped currents into the charge density wave material for such a structure in the tunnelling regime. The transmission and reflection coefficients are also plotted in Figure 6, which bring out the fact that there is no transport in the tunnelling regime. The plot clearly brings out the differences as the rectified currents in the tunnelling regime are exactly zero while a finite pumped current exists. The expression for the pumped current can also be easily derived in the weak pumping regime $\zeta_p \ll \zeta_0$ and $\chi_p \ll \chi_0$ (see Eq. 4), and in tunnelling regime, i.e., the limit where $E \ll \Delta$.

The unique thing of such a normal metal-insulator-superconductor structure is that the macroscopic phase ($\chi$) of the charge density wave appears in the expression for the transmission $|t|^2$ and reflection $|r|^2$ probabilities. This is in sharp contrast to a normal metal-insulator-superconductor structure where the macroscopic phase of the superconductor does not appear in the transmission and reflection probabilities. Here of course we are interested in the distinct characteristics of the rectified current and the pumped current. The unique thing of our structure is that in the tunnelling regime for $E \ll \Delta^2$, the system does not conduct (as $|t|^2 = 0$, see Fig. 6) but pumps a finite current as in Fig. 7. This is because the transmission probability is zero which can easily be seen also from the above equation, while in the same regime there is a finite pumped current.

In the above expressions, $w = \sqrt{E^2 - \Delta^2}$, $w' = i\sqrt{\Delta^2 - E^2}$ and $z = V/\hbar v_F$, with $q = E/\hbar v_F$ and $k = w/\hbar v_F$ in the propagating regime while $k = iw'/\hbar v_F$ in the tunnelling regime, $\chi$ is phase of the charge density wave.

The unique thing of such a normal metal-insulator-superconductor structure is that the macroscopic phase of the superconductor does not appear in the transmission and reflection probabilities. Here of course we are interested in the distinct characteristics of the rectified current and the pumped current. The unique thing of our structure is that in the tunnelling regime for $E \ll \Delta^2$, the system does not conduct (as $|t|^2 = 0$, see Fig. 6) but pumps a finite current as in Fig. 7. This is because the transmission probability is zero which can easily be seen also from the above equation, while in the same regime there is a finite pumped current. To invoke pumping in this structure we modulate the strength of the delta function barrier ($z = z_0 + \zeta_p \sin(wt)$) and the phase of the charge density wave order parameter ($\chi = \chi_0 + \chi_p \sin(wt + \phi)$).

In Fig. 7, we plot the pumped currents into the charge density wave material for such a structure in the tunnelling regime. The transmission and reflection coefficients are also plotted in Figure 6, which bring out the fact that there is no transport in the tunnelling regime. The plot clearly brings out the differences as the rectified currents in the tunnelling regime are exactly zero while a finite pumped current exists. The expression for the pumped current can also be easily derived in the weak pumping regime $\zeta_p \ll \zeta_0$ and $\chi_p \ll \chi_0$ (see Eq. 4), and in tunnelling regime, i.e., the limit where $E \ll \Delta$.

In the above expressions, $w = \sqrt{E^2 - \Delta^2}$, $w' = i\sqrt{\Delta^2 - E^2}$ and $z = V/\hbar v_F$, with $q = E/\hbar v_F$ and $k = w/\hbar v_F$ in the propagating regime while $k = iw'/\hbar v_F$ in the tunnelling regime, $\chi$ is phase of the charge density wave.

The unique thing of such a normal metal-insulator-superconductor structure is that the macroscopic phase of the superconductor does not appear in the transmission and reflection probabilities. Here of course we are interested in the distinct characteristics of the rectified current and the pumped current. The unique thing of our structure is that in the tunnelling regime for $E \ll \Delta^2$, the system does not conduct (as $|t|^2 = 0$, see Fig. 6) but pumps a finite current as in Fig. 7. This is because the transmission probability is zero which can easily be seen also from the above equation, while in the same regime there is a finite pumped current. To invoke pumping in this structure we modulate the strength of the delta function barrier ($z = z_0 + \zeta_p \sin(wt)$) and the phase of the charge density wave order parameter ($\chi = \chi_0 + \chi_p \sin(wt + \phi)$).

In Fig. 7, we plot the pumped currents into the charge density wave material for such a structure in the tunnelling regime. The transmission and reflection coefficients are also plotted in Figure 6, which bring out the fact that there is no transport in the tunnelling regime. The plot clearly brings out the differences as the rectified currents in the tunnelling regime are exactly zero while a finite pumped current exists. The expression for the pumped current can also be easily derived in the weak pumping regime $\zeta_p \ll \zeta_0$ and $\chi_p \ll \chi_0$ (see Eq. 4), and in tunnelling regime, i.e., the limit where $E \ll \Delta$.

In the above expressions, $w = \sqrt{E^2 - \Delta^2}$, $w' = i\sqrt{\Delta^2 - E^2}$ and $z = V/\hbar v_F$, with $q = E/\hbar v_F$ and $k = w/\hbar v_F$ in the propagating regime while $k = iw'/\hbar v_F$ in the tunnelling regime, $\chi$ is phase of the charge density wave.

The unique thing of such a normal metal-insulator-superconductor structure is that the macroscopic phase of the superconductor does not appear in the transmission and reflection probabilities. Here of course we are interested in the distinct characteristics of the rectified current and the pumped current. The unique thing of our structure is that in the tunnelling regime for $E \ll \Delta^2$, the system does not conduct (as $|t|^2 = 0$, see Fig. 6) but pumps a finite current as in Fig. 7. This is because the transmission probability is zero which can easily be seen also from the above equation, while in the same regime there is a finite pumped current. To invoke pumping in this structure we modulate the strength of the delta function barrier ($z = z_0 + \zeta_p \sin(wt)$) and the phase of the charge density wave order parameter ($\chi = \chi_0 + \chi_p \sin(wt + \phi)$).

In Fig. 7, we plot the pumped currents into the charge density wave material for such a structure in the tunnelling regime. The transmission and reflection coefficients are also plotted in Figure 6, which bring out the fact that there is no transport in the tunnelling regime. The plot clearly brings out the differences as the rectified currents in the tunnelling regime are exactly zero while a finite pumped current exists. The expression for the pumped current can also be easily derived in the weak pumping regime $\zeta_p \ll \zeta_0$ and $\chi_p \ll \chi_0$ (see Eq. 4), and in tunnelling regime, i.e., the limit where $E \ll \Delta$.

In the above expressions, $w = \sqrt{E^2 - \Delta^2}$, $w' = i\sqrt{\Delta^2 - E^2}$ and $z = V/\hbar v_F$, with $q = E/\hbar v_F$ and $k = w/\hbar v_F$ in the propagating regime while $k = iw'/\hbar v_F$ in the tunnelling regime, $\chi$ is phase of the charge density wave.

The unique thing of such a normal metal-insulator-superconductor structure is that the macroscopic phase of the superconductor does not appear in the transmission and reflection probabilities. Here of course we are interested in the distinct characteristics of the rectified current and the pumped current. The unique thing of our structure is that in the tunnelling regime for $E \ll \Delta^2$, the system does not conduct (as $|t|^2 = 0$, see Fig. 6) but pumps a finite current as in Fig. 7. This is because the transmission probability is zero which can easily be seen also from the above equation, while in the same regime there is a finite pumped current. To invoke pumping in this structure we modulate the strength of the delta function barrier ($z = z_0 + \zeta_p \sin(wt)$) and the phase of the charge density wave order parameter ($\chi = \chi_0 + \chi_p \sin(wt + \phi)$).

In Fig. 7, we plot the pumped currents into the charge density wave material for such a structure in the tunnelling regime. The transmission and reflection coefficients are also plotted in Figure 6, which bring out the fact that there is no transport in the tunnelling regime. The plot clearly brings out the differences as the rectified currents in the tunnelling regime are exactly zero while a finite pumped current exists. The expression for the pumped current can also be easily derived in the weak pumping regime $\zeta_p \ll \zeta_0$ and $\chi_p \ll \chi_0$ (see Eq. 4), and in tunnelling regime, i.e., the limit where $E \ll \Delta$.
In-contrast the pumped current is finite and in figure 8 we can see from Eq. 18, for either $\chi = 0$ or $\chi = \pi/2$ there is no pumped current similar to the pumped current into the CDW material.

The experimental realization of our structure won't be difficult. Mesoscopic charge density wave interfaces have been around for quite awhile now. A metallic gate electrode subject to an oscillating gate voltage is placed on top of the charge density wave material, this arrangement can be effectively used to modulate the phase of the charge density wave. Of course a very similar structure to that which is envisaged here has been experimentally realized by Adelman, et. al., in Ref. [36]. In the experiment of Adelman, et. al., electric field induced variations of the charge density wave order parameter lead to modulation of the conductance. Further to modulate the interface delta function barrier one can apply an oscillating voltage at the interface. The experimental viability of this structure is of course guaranteed since such type of make-up was theoretically envisaged to provide for a charge density wave ratchet. The only difference will be quantum interference effects dominating and the time dependent voltages being in the adiabatic regime, i.e., at very low temperatures and the system being in the mesoscopic regime.

Finally to conclude this section it should be noted that these three examples may not be unique there might be many other examples of the distinctive nature of the rectified and pumped currents which can be easily and unambiguously detected in experiments.

3 Conclusions

To conclude we have provided three examples in which the pumped and rectified currents are so very distinct. These examples provide an alternative and perhaps better way to distinguish the rectified and pumped currents since these go beyond looking just at the magnetic field symmetry of the currents. The distinctive properties of the rectified and pumped currents will also breakdown if the mesoscopic scatterer has distinct spatial symmetries. In that case looking at the magnetic field symmetry of the currents wont provide the solution. In the first example given above the rectified currents are completely unpolarized while the pumped currents are pure spin polarized, in the second example we have net zero rectified currents for equal strengths of the potential barriers while in example three the rectified currents do not exist at all in the tunnelling regime while the system pumps a definite amount of current both in to the charge density wave material and the normal metal lead.

4 Acknowledgments

The author would like to thank Prof. G. E. W. Bauer for kindly sending reference [33]. The author also thanks the organizers of the workshop on Quantum information and decoherence at Benasque, Spain from June 26-July 15 for providing funds to attend. A major portion of the work was completed there.
