ABSTRACT
We present optical spectroscopy of EX Hya during its 1991 outburst. This outburst is characterized by strong irradiation of the front face of the secondary star by the white dwarf, an overflowing stream which is seen strongly in HeII λ4686 and by a dip in the light curves, which extends from 0.1 to 0.6 in the binary and spin phases. Strong irradiation of the accretion curtain and that of the inner regions of the disc led to strong emission of HeII λ4686 and to the suppression of the Hγ and Hβ emission.

Disc overflow was observed in quiescence in earlier studies, where the overflow stream material was modulated at high velocities close to 1000 km s$^{-1}$. In outburst, the overflowing material is modulated at even higher velocities ($\sim$1500 km s$^{-1}$). These are streaming velocities down the field lines close to the white dwarf. Evidence for material collecting near the outer edge of the disc and corotating with the accretion curtain was observed. In decline, this material and the accretion curtain obscured almost all the emission near binary phase 0.4, causing a dip. The dip minimum nearly corresponds with spin pulse minimum. This has provided additional evidence for an extended accretion curtain, and for the corotation of material with the accretion curtain at the outer edge of the disc. From these observations we suggest that a mechanism similar to that of Spruit and Taam, where outbursts result due to the storage and release of matter outside the magnetosphere, triggers the outbursts of EX Hya. This is followed by the irradiation of the secondary star due to accretion induced radiation.

Key words: accretion, accretion discs – binaries: close – novae, cataclysmic variables.

1 INTRODUCTION
EX Hya is an eclipsing binary system and an intermediate polar (IP), a subclass of magnetic cataclysmic variable stars where a white dwarf star accretes material from a late-type main sequence star, or the secondary, as the two stars orbit about their common centre of mass under the influence of their mutual gravitation.

EX Hya has a spin period ($\sim$67.03 min) which is about 2/3 its orbital period (98.26 min; Mumford 1967; Hellier, Mason & Rosen 1987) and has its accretion curtains extending to the outer edge of the accretion disc (hereafter the accretion ring or the ring) near the Roche lobe radius (King & Wynn 1999; Wynn 2000; Belle et al. 2002; Norton, Wynn & Somerscales 2004; Belle et al. 2005; Mhlahlo et al. 2007). Recently, Mhlahlo et al. (2007) showed that near the Roche lobe radius the accretion curtains corotate with part of the accretion ring and a combination of stream and ring accretion (ring overflow) was explained well by the observations.

EX Hya is one of the few IPs that undergo brief outbursts, nearly once every 1.5 yr (Hellier et al. 2000). Previous spectral studies of EX Hya in outburst have been characterized mainly by two events: the development of a broad-base component of the emission lines on the night of outburst, possibly modulated at the orbital period (Hellier et al. 1989), and the significant decrease, or even absence, of the modulation at the spin pulse (Bond et al. 1987; Hellier et al. 1989).

Studies done by Hellier et al. (1989) during the 1987 outburst of EX Hya revealed a broad-base component (the ‘base excursion’) that appeared to be modulated at the orbital period. The ‘base excursion’ was phased with maximum blueshift at orbital phase $\phi_{OB} \sim 0.4$ and was interpreted as being caused by the stream of material overflowing the initial impact with the disc and free-falling on to the magnetosphere of the white dwarf. These results were confirmed during an outburst of EX Hya in 2000 where an X-ray heat pulse was discovered and eclipse of the overflow stream material by the secondary was observed (Hellier et al. 2000).

During the 1991 outburst a dip feature was observed in the light curves in decline, where almost all the emission was obscured.

⋆E-mail: nceba@maia.saao.ac.za
around phase $\phi_{07} \sim 0.4$ (Buckley 1992). No interpretation was provided for this dip.

Five other IPs that have been reported to undergo outbursts are XY Ari (Hellier et al. 1997), GK Per (Sabbadin & Bianchini 1983; Watson, King & Osborne 1985; Morales-Rueda, Stitt & Roche 1996), TV Col (Szkody & Mateo 1984; Hellier & Buckley 1993), V1223 Sqr (van Amerongen & van Paradijs 1989) and YY Dra (Szkody et al. 2002). XY Ari, GK Per and YY Dra are said to have their outbursts caused by an instability in the disc (Hellier et al. 1997) while the other three IPs, TV Col, V1223 Sqr and EX Hya, seem to pose problems for the disc instability model. It has been suggested that the outbursts in these three stars are a result of increased mass transfer from the secondary (Hellier & Buckley 1993; Hellier et al. 1989, 2000). An alternative is that the enhanced mass transfer could be a result of increased irradiation of the secondary, which in turn is a consequence of a disc instability (Hellier et al. 2000).

With these questions in mind, we present the outburst data of EX Hya and the analysis in Sections 2–6.2, we investigate the cause of the dip seen in the light curves in Section 7 and we discuss and interpret the results in Section 8.

### 2 OBSERVATIONS AND DATA REDUCTION

In this section we present spectroscopic data obtained in 1991 at the South African Astronomical Observatory (SAAO) when EX Hya was in outburst.

This occurred on 1991 April 27/28 and was observed using the SAAO 1.9-m telescope with the Reticon photon counting system detector on the Cassegrain spectrograph by Buckley et al. (1991). A wavelength range of 4000–5080 Å was covered at a spectral resolution of $\Delta \lambda \sim 1.2$ Å and at a time resolution of 100–120 s. The spectrograph slit width was 250 µm ($\sim 1.5$ arcsec). Wavelength calibration exposures were taken using a CuAr arc lamp. Five nights of observations (1991 April 24, 25, 27, 28 and 29) were covered and in total 572 spectra were obtained. The observing log is given in Table 1 showing the starting times of the observations, the data length and the number of spectra obtained on each night [the data of Buckley et al. (1991) and Buckley (1992)]. Following the wavelength calibration and sky subtraction, the data were flux calibrated using the spectra of the standard star LTT3864.

Preliminary analysis of the data was done and initial results were published by Buckley et al. (1991) and Buckley (1992). The data were archived and have been retrieved for a more detailed analysis, presented here.

### 3 THE VISUAL LIGHT CURVES

The 1991 outburst of EX Hya started on April 27/28, with the system rising from $V \sim 13$ to $\sim 10$ mag. The outburst lasted for $\sim 1$–2 d, during which EX Hya increased in brightness by $\sim 3$ mag. Fig. 1 shows the visual light curves, with the times of our spectroscopic observations represented by arrows; they represent an average of start and end times of our observations of each night. The visual light-curve data were supplied by the Variable Star Section of the Royal Astronomical Society of New Zealand (VSS RASNZ).

### 4 THE EMISSION-LINE PROFILES

Fig. 2 shows the summed spectra of EX Hya during rise to outburst, in outburst and during decline to quiescence. The spectra have been normalized by the continuum to aid comparison. Prominent peaks in the spectra are those of the H$\beta$ and H$\gamma$. As was reported by Buckley et al. (1991), the strengthening of all the emission lines is evident during outburst. The He$\text{II}\lambda 4686$ line, which was weak in quiescence, emerges stronger and broad in outburst, while the He$\text{I}\lambda 4471$ shows a strong central absorption component on the night following outburst. The H$\beta$ and H$\gamma$ emission lines are double-peaked and seem to be broader in quiescence than in outburst.

The line profile widths showed a significant decrease during outburst, by $\sim 33$ per cent for H$\beta$, $\sim 50$ per cent for H$\gamma$ and $\sim 50$ per cent for He$\text{I}\lambda 4471$ (not shown), when compared to the linewidths in quiescence of 1991; and by $\sim 50$ per cent for H$\beta$ and H$\gamma$ and by $\sim 55$ per cent for He$\text{I}\lambda 4471$ (not shown), when compared with the linewidths in quiescence of 2001 (see Fig. 3). An increase in the widths of the emission lines, with respect to outburst, by $\sim 20$ per cent in H$\beta$ and H$\gamma$ (Fig. 3) and by $\sim 33$ per cent in He$\text{I}\lambda 4471$ (not shown), was observed during decline. We find a full width at half-maximum of $\sim 38$ Å for both H$\beta$ and H$\gamma$ in quiescence and $\sim 20$ Å for both emission lines in outburst. The full width at zero intensity was found to be $\sim 3000$ km s$^{-1}$ for H$\beta$ and $\sim 3400$ km s$^{-1}$ for H$\gamma$ in outburst, compared to that of $\sim 7000$ km s$^{-1}$ ($\sim 180$ Å) in quiescence, for both the H$\beta$ and H$\gamma$ emission lines (see Table 1).

### Table 1. Spectroscopic observations during the 1991 outburst. Column 3 denotes the number of hours of observations, column 4 the number of spectra obtained and column 5 denotes the state whether it is outburst (o), decline (d) or quiescence (q). A grating with a resolution of 1200 mm$^{-1}$ was used and covered a wavelength range of 4000–5080 Å.

| Date       | HJD (start) | Number of hours | Number of spectra | State |
|------------|-------------|-----------------|-------------------|-------|
| 1991 April 24 | 244 8371.3884097 | 3.28            | 90                | q     |
| 1991 April 25 | 244 8372.3603850 | 2.93            | 72                | q     |
| 1991 April 27 | 244 8374.2808828 | 5.45            | 160               | o     |
| 1991 April 28 | 244 8375.2925521 | 5.49            | 150               | d     |
| 1991 April 29 | 244 8376.2402973 | 7.00            | 100               | q     |

Outbursts of EX Hydrae revisited

5 THE ORBITAL RADIAL VELOCITIES

The radial velocities in outburst of 1991 were obtained using the Gaussian Convolution Scheme (GCS) (e.g. Shafter & Szkody 1984; Shafter 1985). The GCS method convolves each spectrum with two identical Gaussians, one in the red wing and the other in the blue wing. The separation between the two Gaussians is 2σ (see also Mhlaha et al. 2007). The radial velocities were measured from the wings and the core of the Hβ, Hγ and He II λ4686 emission lines from every individual spectrum, and the data were used to determine the periods from discrete Fourier transforms (DFTs) (Deeming 1975; Kurtz 1985).

6 ORBITAL VARIATIONS OF THE EMISSION LINES IN OUTBURST

All the radial velocity data were phase-folded on the orbital ephemeris of Hellier & Sprouts (1992) which is defined by the zero phase being mid-eclipse. For the radial velocities, maximum blueshift occurs at phase 0.75 when viewing is perpendicular to the line of centres. 50 phase intervals were used.

6.1 Doppler tomograms and trailed spectra

The maximum entropy method (MEM) (Spruit 1998) was used to construct the orbital Doppler tomograms, using the phase binned data. For each spectrum an average was taken and subtracted from the spectrum to emphasize the bright spot and secondary star emission. The Hβ, Hγ, He I λ4471 and He II λ4686 tomograms and
Figure 6. Hβ and Hγ trailed spectra in outburst and during decline are shown (top panels). MEM orbital tomograms are shown in the second panels with the average-subtracted trailed spectra shown in the third panels. The emission-line components are identified for Hβ, before and after subtracting the average (the Hγ line shows similar components). All the data are plotted on the same velocity scale. The reconstruction is shown in the bottom. The velocity unit along the x-axis is 10^3 km s^{-1}.

trailed spectra are shown in Figs 6 and 7, and the average-subtracted tomograms are shown in Fig. 8, in outburst and in decline.

In the trailed spectra, a narrow S-wave component (NSC) can be detected in all the emission lines, before and after subtracting the average. The NSC shows maximum blueshift near phase φ_{08} ∼ 0.75 as expected from the motion of the secondary, and an amplitude velocity of ∼400 km s^{-1} (obtained from fitting a Gaussian to the Hβ NSC between phases 0.5 and 1.0). The latter is slightly greater than but close to the K-velocity amplitude of the secondary of K_2 = 360 ± 35 km s^{-1} (Belle et al. 2003; Beuermann et al. 2003; Vande Putte et al. 2003). These observations suggest that the NSC originated from the secondary. The NSC did not originate from the bright spot since it shows a blueshift during binary phases φ_{08} ∼ 0.61–0.85 whereas the NSC resulting from the bright spot is expected to
Figure 7. He I $\lambda$4471 trailed spectra in outburst and during decline, and He II $\lambda$4686 trailed spectra in outburst are displayed. Orbital tomograms are shown in the second panels. The third panels show the trailed spectra after average subtraction and the bottom panels show the reconstruction. The data were folded on the orbital period. The NSC and the ‘arc emission’ (AE) in He I $\lambda$4471 are shown. In He II $\lambda$4686, the dashed line shows the orbital motion of the NSC, and the VHVC is identified in the line wings.
The VHVC is modulated with a velocity of \( \sim 800 \) km s\(^{-1}\) in decline. He I \( \lambda 4471 \) and He II \( \lambda 4686 \) tomograms are shown in the bottom panels.

Outburst tomograms show strong emission at and around the Roche lobe (Fig. 8) for all the emission lines (except for He I \( \lambda 4471 \) where strong emission is seen near \( V_{\perp} = 0 \) than at the Roche lobe), most especially in He II \( \lambda 4686 \), further suggesting that the NSC was mainly caused by the secondary star.

The tomograms (more especially He II \( \lambda 4686 \)) suggest that the emission which lies on the ‘far’ side (relative to the opposite side of the disc, relative to the front face of the secondary), behind the white dwarf, at velocities near \( 800–900 \) km s\(^{-1}\) in decline and can be associated with the HVC seen in the trailed spectra around \( 900 \) km s\(^{-1}\). This HVC is reminiscent of that observed in the tomograms in quiescence (Mhlahlo et al. 2007) on the bottom left-hand quadrant and near the opposite side of the disc, at velocities near \( 800–900 \) km s\(^{-1}\), which originated from the overflow stream.

The He I \( \lambda 4471 \) and He II \( \lambda 4686 \) tomograms are shown in outburst (Fig. 7) shows an enhancement of emission curving away from the secondary along the outer edge of the disc, from \( \phi_{98} = 0 \) (12 o’clock position) to 0.5 (near the 6 o’clock position), in the clockwise direction (hereafter the ‘arc emission’). Between phases \( \phi_{98} = 0.0–0.6 \), the He I \( \lambda 4471 \) trailed spectrum (before subtracting the average) shows strong redshifted emission, resulting from the superposition of the NSC and the ‘arc emission’. At these phases almost all the blueshifted emission is absorbed. Between phases \( \phi_{98} = 0.6 \) and 0.9, the NSC is blueshifted while the ‘arc emission’ is still redshifted. This suggests that the material responsible for the ‘arc emission’ is drifting away from the observer in the radial direction at all orbital phases. During decline, the central absorption feature in He I \( \lambda 4471 \) becomes stronger, and the tomogram no longer shows enhanced emission at the outer edge of the disc.

6.2 The radial velocity curve

The radial velocity data were fitted on the orbital frequency using a fitting function of the form

\[ V(t) = \gamma + K \cos(2 \pi t / P + \phi) \]

where \( t \) is the time in Heliocentric Julian Days (HJDs). Fig. 9 shows a comparison between the Hβ, Hγ, and He II λ4686 NSC and the VHVC. The top panel shows the Hβ VHVC having maximum redshift at \( \phi_{98} \approx 0.79 \) and maximum blueshift at \( \phi_{98} \approx 0.29 \) while the NSC is phased with maximum blueshift at \( \phi_{98} \approx 0.74 \) and lags the VHVC by \( \phi_{98} \approx 0.45 \). The Hγ radial velocity curve (middle panel) shows the VHVC having maximum redshift at \( \phi_{98} \approx 0.81 \) and maximum blueshift at \( \phi_{98} \approx 0.31 \). The NSC is phased with maximum blueshift at \( \phi_{98} \approx 0.7 \) and lags the VHVC by \( \phi_{98} \approx 0.39 \).

The \( \alpha = 700 \) km s\(^{-1}\) curve has an interesting shape as it shows very negative values (\( \sim -350 \) km s\(^{-1}\)) around \( \phi_{98} \approx 0.7 \), indicating that there is streaming material from the accretion stream joining the disc at the bright spot. It is curious that Hγ does not show a similar effect. The He II λ4686 radial velocity curve (bottom panel) shows the VHVC having maximum redshift at \( \phi_{98} \approx 0.74 \) and maximum blueshift at \( \phi_{98} \approx 0.24 \), and the NSC phased with maximum blueshift at \( \phi_{98} \approx 0.79 \) and lags the VHVC by \( \phi_{98} \approx 0.55 \), all in agreement with the behaviour of these components in the trailed spectra.

7 THE ‘DIP’

Buckley (1992) reported on an unusual and sudden temporary drop in flux of EX Hya in decline, which does not coincide with the eclipse time. This is illustrated in Fig. 10 for the He I λ4471 emission line (Hβ, Hγ and the continuum – not shown – show similar results). Buckley (1992) used the orbital and spin ephemerides of Bond et al. (1987) to phase their observations, and we used those of Hellier & Sprouts (1992) to phase ours, and our results predict similar time for the occurrence of the dip. The dip is a real event since the observations were conducted under clear, photometric conditions, and the dip was proven not to be due to telescope drive or guiding errors.

The dip lasts some 30 min (from roughly the time of ingress to that of egress). This dip is reminiscent of that observed in the previous studies of EX Hya, where binary phased light curves show a bulge eclipse which extends over \( \phi_{98} \approx 0.6 - 0.9 \) (Hurwitz et al. 1997; Mauché 1999; Belle et al. 2002) in the extreme ultraviolet (EUV), and around \( \phi_{98} \approx 0.7 - 0.1 \) (Cordova, Mason & Kahn 1985; Rosen, Mason & Cordova 1988) in the X-rays. The bulge is interpreted as an absorption of the EUV emitting region on the white dwarf surface in the EUV photometry. In the optical, extended emission at the outer edge of the ring in the Hα tomogram was observed by Belle et al. (2005), while absorption of the zero-velocity component at \( \phi_{98} \approx 0.6 - 0.9 \) was observed in Hα, Hβ and Hγ (Belle et al. 2005) (see also Mhlahlo et al. 2007). This was interpreted by Belle et al. (2002, 2005) as an indication of the existence of an extended bulge near the outer edge of the ring, from where the extended accretion curtains pull material directly, thereby producing a broad bulge dip in the EUV and the absorption in the optical. The only difference is that the phasing of the structure reported here is reversed (\( \phi_{98} \approx 0.1 - 0.6 \)).

From our observations we make the following deductions and interpretation for the dip.

(i) The fact that the ‘arc emission’ seen in the He I λ4471 orbital tomogram in outburst is always redshifted suggests that the material responsible for this emission is moving away from the observer throughout the orbital phase. This also means the responsible structure/material is changing locations (i.e. always on the side of the observer all around the orbit) rather than being static as in the case of the usual bulge that is normally observed near the bright spot region as discussed above.

(ii) The ‘arc emission’ in outburst extends over spin and binary phases \( \phi_{67.98} \approx 0.1 - 0.6 \). This phasing and the physical extent of the emission are in agreement with those of the dip eclipse observed in decline (Fig. 10). Therefore to explain the dip, there has to be extended emission in the He I λ4471 tomogram in decline similar to that seen in outburst, and the reason we do not observe this emission could be that the responsible material/structure has a high opacity in decline, just as in the EUV case.

(iii) In decline the data are strongly modulated at the spin period (Figs 10 – 12 – see also radial velocity DFTs in Fig. 5) and the fact that the phase of the dip minimum (0.4) nearly corresponds with spin minimum (when the upper accretion curtain is pointing at the observer) suggests that the accretion curtain and its location is strongly related with the structure that is causing the dip.
The structure causing the dip also absorbs zero-velocity emission. Buckley (1992) reported that the HeI $\lambda$4471 central absorption gets stronger before the dip occurs. This further establishes a connection between the dip and the absorption of the zero-velocity emission in HeI $\lambda$4471 during decline.

The fact that this event is not observed to repeat could suggest variations in the optical depth of the bulge associated only with outburst or with the decline phase.

8 DISCUSSION

In this section we compare disc instabilities with mass transfer events and decide, on the basis of our observations, whether outbursts in EX Hya occur via one of the two mechanisms or both or any variation on the two.

According to the generally accepted model, dwarf nova outbursts are caused by an instability in the disc, resulting in the rapid accretion of material on to the surface of the white dwarf. This notion is supported by the argument that the observed flux from the bright spot is similar in quiescence and in outburst. The disc instability model has had success in describing outbursts in dwarf novae. It is thought that the same mechanism may drive outbursts in IPs even though their inner discs are truncated as a result of the relatively strong magnetic field. If outbursts occur via a disc instability, then the fact that EX Hya accretes from a ring of material and the accretion curtains extend to this ring could suggest a different instability, perhaps similar to that described by Spruit & Taam (1993), where outburst cycles result due to storage and release of matter in the parts of the disc just outside the magnetosphere.

Alternative ideas have outbursts caused by a secondary star instability or a burst of mass transfer from the secondary. In at least two IPs, TV Col and EX Hya, the observations of a dramatic increase in the S-wave flux and of overflow stream (EX Hya) in outburst have been taken as evidence for the occurrence of a mass transfer burst (Hellier et al. 1989; Hellier & Buckley 1993). Hellier et al. (1989) claimed that the equivalent width of the S-wave of the emission line was similar in outburst and in quiescence during the time of their observations, and concluded that the flux from the S-wave increased during the 1987 outburst. They saw this as evidence for an increased mass transfer, but it was not conclusive.

There are ‘hybrid models’ which seek to combine disc instabilities with mass transfer events to explain outbursts in SU UMa stars and in most low-mass X-ray binaries, where it is thought that enhanced mass transfer may generate a disc instability, causing an outburst (Lasota, Narayan & Yi 1996). A similar but reversed mechanism has already been suggested as an alternative for EX Hya (Hellier et al. 2000).

In investigating the feasibility of the mass transfer burst models in EX Hya, first we note that our spectroscopy provides evidence for strong irradiation of the secondary star and the inner disc in outburst. All the emission lines have shown strong emission from the secondary Roche lobe. The He II $\lambda$4686 tomograms, on one hand, have revealed a larger ring of emission (in velocity) when compared to those of other emission lines in outburst (Fig. 7). On the other hand, H$\beta$, H$\gamma$ and HeI $\lambda$4471 showed significantly and relatively less inner disc emission and much more from the core during outburst than in quiescence. Correspondingly, the line profile widths have shown a significant decrease in H$\beta$, H$\gamma$ and HeI $\lambda$4471 during outburst, by nearly 33–55 per cent when compared to quiescence (Fig. 3). This suggests irradiation of the inner disc which is possible if the ionization flux due to the UV and soft X-ray emission from the white dwarf was extremely high, as expected in outburst.
In this situation, recombination will be relatively reduced most of the time, resulting in the decrease of line emission or absorption, except for He II \( \lambda 4686 \), which is irradiation driven. Furthermore, the He II \( \lambda 4686 \) tomogram shows an asymmetry on the ‘far’ side, suggesting that most of the disc light comes from this side, which is not eclipsed by the secondary (Coel Holland, private communication).

Observations in decline show an increase in the widths of the emission lines by \( \sim 20 \) per cent (H\( \beta \) and H\( \gamma \)) (Fig. 3) and \( \sim 33 \) per cent (He I \( \lambda 4471 \)). Correspondingly, strong disc emission seen at low velocities in outburst moves to higher velocities during decline, indicating that relatively more emission was received during this period. In addition, relatively more emission from near the bright spot and less from the secondary were observed. All this is an indication that the irradiation of the secondary and that of the disc occurred in outburst and had stopped or decreased during decline.

However, we think that the irradiation of the front face of the secondary (and evidence for disc overflow -- discussed later in the section) is not a strong indication of a secondary instability or an increase in mass transfer. The disc instability model predicts a constant S-wave which is swamped in outburst, while the mass transfer burst model predicts that the bright spot flux will contribute to outburst. The latter model further requires a mass transfer burst which is observationally estimated as \( \sim 2 \times 10^{32} \) g in EX Hya (Hellier & Buckley 1993). This implies a mass transfer rate of \( \sim 8 \times 10^{17} \) g s\(^{-1} \) (averaged over a period of \( \sim 6 \) h near the peak of outburst) and a bright spot luminosity of roughly

\[
L_{\text{sp, outb}} \sim \frac{G M_{d} M(2)}{R_{d}} \sim 2 \times 10^{33} \text{ erg s}^{-1},
\]  

which is lower than the quiescent accretion-induced luminosity of the white dwarf of

\[
L_{\text{acc, q}} \sim 4\pi d^2 \tilde{f}_{d} = 3 \times 10^{32} \text{ erg s}^{-1}\]  

(at a distance of 65 pc Beuermann et al. 2003) by nearly a factor of 10. \( M_{\text{WD}} \) and \( M(2) \) are the mass of the white dwarf and the mass transfer rate from the secondary, respectively, and \( R_{d} \) is the radius of the bright spot. \( L_{\text{sp, outb}} \) is lower than the outburst accretion-induced luminosity

\[
L_{\text{acc, outb}} = \frac{G M_{\text{WD}} M}{2 R_{\text{WD}}} = 2 \times 10^{34} \text{ erg s}^{-1},
\]

where \( \dot{M} \approx 5 \times 10^{33} \) g s\(^{-1} \) is the mass accretion rate (averaged near the peak of outburst, with the mass involved in outburst taken to be \( \sim 10^{33} \) g -- Hellier et al. 2000). For the mass transfer burst idea we would expect \( L_{\text{acc, q}} < L_{\text{sp, outb}} \), as the calculations above confirm (if the numbers were very reliable) since the emission at the bright spot due to the mass transfer burst should be stronger than that from other components in the system. But this is not supported by our observations because the bright spot, which is clearly present in quiescence and in decline, is not observed in outburst, suggesting that it is swamped in outburst. Also, as shown above, \( L_{\text{sp, outb}} < L_{\text{acc, outb}} \). This is not expected in a mass transfer burst situation and this is what our observations seem to support. This observation and arguments counts against the mass transfer burst model.

Also, irradiation of the secondary will not be effective enough to trigger a greatly increased mass transfer since the height, \( h_{d} \), of the outer edge of the ring,

\[
h_{d} \sim 0.038 \rho_{d} M(3/2d)^{1/2} \sim 10^{9} \text{ cm},
\]

for a 0.5 M\(_{\odot}\) white dwarf and for a mass transfer rate \( \dot{M}(d) \) in the disc of \( 0.8 \times 10^{16} \) g s\(^{-1} \) (Warner 1995) is higher than the scaleheight,

\[
H_{d} \sim 1.5 \times 10^{8} \text{ cm},
\]

of a gas column at \( L_{\gamma} \) (Meyer & Meyer-Hofmeister 1983; Kolb & Ritter 1990). This suggests that the shadow of the disc will reduce the irradiation of the surface of the secondary near \( L_{\gamma} \). ((Eisenbart et al. 2002) predicted a disc thickness of \( 2 \times 10^{6} \) cm and a disc radius of \( 1.6 \times 10^{10} \) cm. The latter value is less by nearly a factor of 2 when compared to that of \( \sim 3 \times 10^{10} \) cm obtained by Mhlalo et al. (2007) and Hellier et al. (1987). When the value of disc radius given by Eisenbart et al. (2002) is put in equation (5) then a higher value for \( h_{d} \) (\( \sim 6 \times 10^{10} \) cm) than they predicted is obtained, and so our result obtained from equation (5) above is being considered here).

It is important to point out, though, that the formulae used here are for simple steady state truncated discs and may not necessarily apply properly to EX Hya. But according to our quiescence model of EX Hya (King & Wynn 1999; Belle et al. 2002; Norton et al. 2004; Belle et al. 2005; Mhlalo et al. 2007), the ring of material at the outer edge is disrupted by the field. This should result in the effective disc height at the rim being higher than the value given above since the magnetic field would increase the density of material at the outer disc edge (\( h_{d} \) depends on the temperature, density and local gravity of material). Observational evidence for a bulge in EX Hya at the outer edge of the disc (Mauche 1999; Belle et al. 2002, 2005; Hoogerwerf, Brickhouse & Mauche 2005) and corotating-raised material (Section 7) supports this claim. This bulge is raised by the accretion curtain for nearly half the orbital cycle and so will shadow the \( L_{\gamma} \) point below and above the disc for nearly this period during every orbital cycle. It is therefore unlikely that outbursts are due to a mass transfer event from the irradiation of the secondary surface.

Furthermore, the accretion-induced radiation in outburst (equation 4), will not reach deep into the secondary’s photosphere, since it lies in the EUV and soft X-ray regions where opacities are very large. This radiation will be absorbed by photoionization (Hameury, King & Lasota 1986) and reradiated in high layers of the secondary’s hemisphere, producing strong chromospheric emission. The same emission will irradiate the inner disc and the accretion curtains, giving rise to strong He II \( \lambda 4686 \) emission and to suppression of the Balmer lines which we observe in our data. The radiation in quiescence and that resulting from outburst therefore will not greatly affect the mass transfer rate, other than increasing chromospheric emission. The same is true for the hard X-ray emission in outburst.

Most of our data fit the mechanism of Spruit & Taam (1993). Spruit & Taam (1993) showed that conditions at the inner edge of the disc can cause variations of the magnetostric boundary, and this in turn will result in the accretion near the value of the fastness parameter, \( \omega_{s} = 1 \) (see Section 8.0.1 for a detailed discussion) being unstable. They showed that matter accumulates outside the magnetosphere and, when the gas density in the disc exceeds a critical value, forces the magnetostric boundary inwards, resulting in reduced value of \( \omega_{s} \) (\( \omega_{s} < 1 \)). The latter results in the density at the magnetostric boundary dropping, and the consequent density gradient at the magnetostric radius causes an increase in the mass flow. Matter is then forced to accrete and its depletion leads to the surface density of the magnetostric boundary decreasing. The magnetostric boundary consequently is forced outward to radii corresponding to \( \omega_{s} > 1 \) at a reduced accretion rate, sweeping up material from the disc and forcing it to corotate with it. When sufficient mass has piled up at the inner region of the accretion disc it pushes the magnetosphere back to \( \omega_{s} < 1 \), and the cycle repeats nearly on a viscous time-scale. Spruit & Taam (1993) pointed out that their model could be applied to IPs. This was taken up
by Warner (1996) who suggested that this model can be applied to EX Hya.

Our data fit this mechanism as follows.

(i) Measurements of peak-to-peak separation of \( \sim 700 \text{ km s}^{-1} \) (estimated from a double-Gaussian fit of the H\( \beta \) emission line) have indicated a rotational velocity of \( \sim 350 \text{ km s}^{-1} \), leading to a radial distance from the white dwarf to the outer edge of the ring of \( \sim 5 \times 10^{10} \text{ cm} \), which is \( \sim a \), the binary separation (for a white dwarf mass of 0.5 M\( \odot \); Keplerian motion about the white dwarf at the outer edge of the disc was assumed). As discussed in Mhlahlo et al. (2007), the disc is disrupted by the field near \( \sim 3 \times 10^{10} \text{ cm} \) and so the ring which extends from this distance to near \( a \) has a width of \( \sim 2 \times 10^{10} \text{ cm} \).

The brightening at the outer edge of this ring is observed in the outburst tomograms, except in He\( ii \ \lambda 4686 \) (Figs 6 and 7), and there are indications that the ring of material was extended in outburst. In addition, the He\( ii \ \lambda 4471 \) orbital tomograms show an ‘arc emission’ near \( \sim 350 - 400 \text{ km s}^{-1} \), covering about half the orbital phase. This can be accepted as evidence that some material had accumulated at the outer edge of the ring.

(ii) The orbital trailed spectra have shown redshifted emission which can be associated with the ‘arc emission’ in the tomograms, near the outer ring. This emission is observed throughout the entire orbital cycle in outburst, while the blueshifted emission is obscured by the accretion curtain, when it is on the side of the observer and when it is farthest from the observer. This is evidence for the ring material drifting away from the observer (suggesting that the material is drifting towards the field lines of both the lower and the upper poles). This is also evidence for the corotation of some of this material with the accretion curtains [see (i)–(vi) in Section 7].

(iii) Our discovery of He\( ii \ \lambda 4686, \ H\beta \) and H\( \gamma \) emission on the upper accretion curtain at higher velocities than in quiescence, when the primary was between the upper accretion curtain and the secondary (Fig. 8), provided evidence for disc overflow accretion. This emission was modulated at \( \pm 1500 \text{ km s}^{-1} \) in quiescence it was measured at \( \pm 1000 \text{ km s}^{-1} \), suggesting that the overflow material hit the magnetosphere much closer to the white dwarf. The VHVC was modulated at the orbital period (Figs 4 and 9) since the accretion curtains pick up material mostly when it is fed favourably from the stream, that is, on the side facing the magnetic pole. The phasing of the VHVC (maximum blueshift at \( \phi_{385} \sim 0.3 - 0.4 \)) is consistent with the expected phase of impact of a stream with the magnetosphere, and the phase lag between the H\( \beta \), H\( \gamma \) and He\( ii \ \lambda 4686 \) NSC and VHVC of \( \sim 180^\circ \) is consistent with the motion of the region hit by the overflow stream on the magnetosphere (i.e. the region behind the white dwarf relative to the front face of the secondary) being antiphased with the motion of the secondary.

The radial velocities show large negative values of \( \gamma \)-velocities in the blue for He\( ii \ \lambda 4686 \) (\( -304 \text{ km s}^{-1} \) when compared to \( -67 \text{ km s}^{-1} \) for H\( \beta \)) which indicates streaming velocities much closer to the white dwarf (Buckley et al. 2000). In previous studies of EX Hya (Hellier et al. 1989, 2000), the observation of the overflow stream during outburst was interpreted as evidence for enhanced mass transfer. We point out that the fact that the overflow stream was modulated at higher velocities in outburst than in quiescence suggests that the radius of the magnetosphere decreased, and so the overflow material hits the magnetosphere closer to the white dwarf than when the accretion curtain is extended (Fig. 13).

(iv) The VHVC which was prominent in outburst was not present in decline, instead, an HVC (near \( \sim 1000 \text{ km s}^{-1} \)) was observed and this, by parity of reasoning [see (iii) above], indicates that the overflow stream hit the magnetosphere far from the white dwarf as is the case in quiescence (Mhlahlo et al. 2007) due to the magnetospheric boundary having been forced outwards.

8.0.1 Revised outburst model of EX Hya

We therefore propose that outbursts in EX Hya are triggered by a mechanism similar to that suggested by Spruit & Taam (1993) as illustrated in the rough sketches in Fig. 13.

If so then this would imply that mass was stored in the outer ring near \( \omega_{a} > 1 \), as suggested by observations, where \( \omega_{a} = \frac{H_{a}}{\omega_{1}} \) is the dimensionless stellar angular velocity or the fastness parameter, \( \omega_{1} \) is the spin angular velocity of the white dwarf and \( \Omega_{K}(r_{a}) \) is the Keplerian angular velocity at the inner radius \( r_{a} \) of the disc. Where the inner edge of the ring of EX Hya coincides with the corotation radius, \( \omega_{a} = 0.329\mu(1.31)^{5/3}M_{WD}^{-1/5}P_{3,\text{spin}}^{-1}M_{17}^{3/7} \sim 1 \), assuming a magnetic moment of \( 5 \times 10^{33} \) (Norton et al. 2004), and \( M_{3,\text{spin}} \sim 0.1 \times 10^{17} \text{ g s}^{-1} \) (Fujimoto & Ishida 1997; Hellier et al. 2000).\( P_{3,\text{spin}} \) is in units of \( 10^{3} \) s. At this \( \omega_{a} \) the material is moving with a velocity

\[
\dot{v}_{a}(r_{a}) = \frac{943}{\omega_{a}P_{3,\text{spin}}}^{1/3} \sim 500 \text{ km s}^{-1},
\]

(Warner 1995), where here \( M_{WD} \) is in units of M\( \odot \) (solar masses), in agreement with our observation in quiescence (Belle et al. 2005; Mhlahlo et al. 2007).

The amount of material transferred from the secondary to the disc (with a small percentage overflowing the disc) over the recurrence interval (\( \sim 1.5 \text{ yr} \)) can be estimated to be \( \sim 1 \times 10^{22} \) g [assuming \( M(2) \sim 2 \times 10^{15} \text{ g s}^{-1} \) (Norton et al. 2004)], which suggests that over this period of time there will be enough stored material in the ring (\( \geq 10^{22} \text{ g} \) – Hellier et al. 2000) to trigger an outburst.

The viscous time-scale at \( r_{\gamma} \), predicted by this model is \( t_{\gamma} = 1/M_{\gamma} \Omega_{K} \sim 7 \text{ h} \), where \( M_{\gamma} = 0.03 \text{ g s}^{-1} \). This is low by nearly a factor of 2 when compared to the observed rise time in EX Hya of \( \leq 12 \text{ h} \) (Hellier et al. 1989, 2000).

No prediction for the recurrence time is possible using the Spruit & Taam (1993) model. However, it is worth noting that in this model outbursts are due to accumulation of mass, but because there is a lot of mass falling on to the white dwarf all the time in EX Hya, it takes long to accumulate enough mass to trigger an outburst, leading to a long recurrence period. Dwarf novae accumulate mass most of the time and so outbursts recur on a time-scale of \( \sim 30 \text{ d} \) to a few months.

8.1 Summary

From our analysis we have shown that strong irradiation of the secondary star and that of the inner regions of the disc took place in outburst and that most of the H\( \beta \) and H\( \gamma \) inner ring and accretion curtain emission was suppressed during outburst.

Evidence for the stream of material overflowing the initial impact with the accretion disc and impacting on to the magnetosphere of the white dwarf star was observed. In outburst, the overflow material was observed to be modulated at even higher velocities (\( \sim 1500 \text{ km s}^{-1} \)) than in quiescence, which are streaming velocities close to the white dwarf. This suggests a decrease in the magnetospheric radius.

We showed that the outburst did not occur via the \( M \) instability nor was there any increased mass transfer due to irradiation of the front face of the secondary. It is clear that the strong irradiation of the...
Outbursts of EX Hydrae revisited

Figure 13. A schematic drawing of EX Hya just before outburst (a) showing material accumulating near $r_{in}$ and forced to corotate with the magnetosphere at the inner edge of the ring. Diagram (b) depicts a situation during outburst, after the magnetosphere has been pushed inwards, and in decline before the magnetosphere is forced outwards. The emission region on the magnetosphere due to impact by the overflowing stream of material is depicted. The inner regions of the disc and the accretion curtains emitted relatively less H$\beta$ and H$\gamma$ but relatively more HeII $\lambda 4686$ emission due to irradiation. Most of this emission came from the rear side of the disc. The stream emission hit the magnetosphere closer to the white dwarf during outburst (VHVC) than in quiescence (HVC).

front face of the secondary resulted in chromospheric emission. We suggest that the amount of matter stored in the outer ring is enough to trigger a disc instability of the form suggested by Spruit & Taam (1993), and have shown evidence for the existence of such matter near the Roche lobe. We explained the dip during decline as due to the optically thick extended accretion curtains and the corotating material near the Roche lobe radius obscuring the emission from the white dwarf.

Comparison studies of EX Hya and the EX Hya-like system, V1025 Cen, in quiescence and in outburst, will increase our understanding of accretion dynamics and processes in these systems, and further confirm the extended accretion curtain theory.

ACKNOWLEDGMENTS

NM would like to acknowledge financial support from the Sainsbury/Linsbury Fellowship Trust and the University of Cape Town. NM would also like to thank Frank Bateson and W. Allen of the Variable Star Section of the Royal Astronomical Society of New Zealand for supplying visual observations. We would also like to thank Kunegunda Belle and Coel Hellier for invaluable discussions and for their constructive comments. We acknowledge use of D. O’Donoghue’s and Tom Marsh’s programs EAGLE and MOLLY, respectively. BW is supported by research funds from the University of Cape Town.
