Abstract—Non-geostationary (Non-GSO) satellite constella-
tions have emerged as a promising solution to enable ubiqui-
tous high-speed low-latency broadband services by generat-
ing multiple spot-beams placed on the ground according to the user
locations. However, there is an inherent trade-off between
the number of active beams and the complexity of generating a large
number of beams. This paper formulates and solves a joint beam
placement and load balancing problem to carefully optimize the
satellite beam and enhance the link budgets with a minimal
number of active beams. We propose a two-stage algorithm
design to overcome the combinatorial structure of the considered
optimization problem providing a solution in polynomial time.
The first stage minimizes the number of active beams, while the
second stage performs a load balancing to distribute users in
the coverage area of the active beams. Numerical results confirm
the benefits of the proposed methodology both in carrier-to-noise
ratio and multiplexed users per beam over other benchmarks.

I. INTRODUCTION

Non-geostationary (Non-GSO) satellite communication sys-
tems are expected to play an important role in future global
wireless communications [1]. Both low Earth orbit (LEO) and
medium Earth orbit (MEO) constellations are revolutionizing
the satellite broadband market [2]. The main benefit of such
networks resides mainly on their proximity to Earth, which
translates into much lower latency than their GSO satellite
counterparts. These constellations are equipped with the latest
advances in payload and antenna design, including radio
resource adaptability and beamforming capabilities [3].

Resource allocation problems in satellite communication
typically include, for example, (i) beam footprint design; (ii)
user-to-beam assignment; and (iii) allocating limited radio
resources to each satellite beam such that users’ demands
should be satisfied. In the literature, several works have inves-
tigated the resource allocation problems for the multi-beam
satellite systems comprising power control [4], frequency
assignment [5], joint power and bandwidth allocations [6],
and application of deep reinforcement learning [7]. Regrading
beam footprint design, certain works have aimed at a fully-
flexible beamforming design [8] which is not practical in
terms of complexity, particularly for the fast pass times of
LEO and MEO satellites. Herein, we focus on a practical
scenario which is based on the actual functioning mode of
operational Non-GSO satellites. In particular, we consider the
beam placement problem, where the conical-shaped beams are
predefined in half power beam width (HPBW) and its location
on the coverage area needs to be defined. The beam placement
problem optimizes the number of users to each satellite beam
together with the beam center. Recently, the different beam
placement problems have been studied for LEO constellations
in [9]. These related works proposed heuristic algorithms to
find the number of active beams to strategically and effectively
use satellite resources. Although the proposed algorithms can
find the number of active beams at the satellite, an unbalanced
load appears between the beams. Specifically, the significantly
different number of users among the active beams results in a
heavy load of a few beams. The unbalanced load becomes
severe when many users simultaneously request to access
some particular beams, while the other active beams are being
in a sparse situation with only a few users. To overcome this
issue, linear techniques for the beam layout design in multi-
beam satellite systems were proposed in [10]. The multi-spot
beam arrangement approach was studied in [11] to determine
how the distances between two spot beams enhances the
system performance. These works have not classified users
into individual beams and specified the active beam number.

Inspired by the above discussions, this paper formulates a
weighted sum minimization problem for the beam placement
and load balancing issue in the Non-GSO satellite systems
to jointly optimize the required number of active beams and
the connection quality between the users and the satellite.
The main contributions of this paper are summarized as: (i)
We formulate a novel optimization problem to minimize the
distance from the users to their served beam center with
the minimal number of active satellite beams. We emphasize
that this non-convex and NP-hard optimization has not been
investigated in the literature yet; (ii) We propose a two-
stage algorithm for efficient and practical implementations in
polynomial time: We first propose an algorithm to find the
minimum number of active beams required to cover all the
users at least with the HPBW. Next, we refine the solution of
the first step targeting a balanced number of user per beam;
and (iii) We provide experimental results to demonstrate the
effectiveness of the proposed algorithm and compare with
available benchmarks in the literature.

II. MULTI-BEAM SATELLITE SYSTEM MODEL

A multi-beam multi-user Non-GSO satellite system is con-
considered in this paper, as illustrated in Fig. 1. The gateway
located on the ground is connected to the satellite through
an ideal feeder link and the beam placement optimization

This work was supported by the Luxembourg National Research Fund
(FNR) under the project INtegrated Satellite - TeRrestrial Systems for
Ubiquitous Beyond 5G CommunicatIons (INSTRUCT).
is handled at the gateways. Specifically, a satellite equipped with an antenna array that enables to create a maximum of $N$ beams to serve $K$ users in the coverage area with $N \geq K$. Due to a limited power budget at the satellite and mutual interference especially at the beam boundary, it is not always beneficial to activate all the beams. Consequently, let us denote $B \subseteq \{1, \ldots, N\}$ the set of active satellite beam indices with $|B| \leq N$. In addition, we denote $K = \{1, \ldots, K\}$ the set of user indices. With a proper scheduling design, the $K$ users are assigned into the active satellite beams for which $K_b \subseteq K$, $b \in B$, contains the indices of the users served by the $b$-th active beam. The following property is established as

$$K_b \neq \emptyset, K_b \cap K_{b'} = \emptyset, \forall b, b' \in B, \text{ and } \bigcup_{b=1}^{|B|} K_b = K,$$

which indicates that each beam should serve at least one user. Let us denote $\theta_{b,k}$ ($0 \leq \theta_{b,k} \leq \pi/2$) the angle between the spot beam center of the $b$-th beam and the UE's location, $k \in K_b$, as seen from the satellite. Then, the radiation pattern from the $b$-th beam to UE$_k$ can be mathematically formulated as a function of $\theta_{b,k}$, which is reported in the 3GPP [12] as

$$g_{b,k} = \max g(\theta_{b,k}), \forall k \in K_b, b \in B,$$

where $g_{b,k}^{\max}$ is the maximum beam pattern gain that is obtained if UE$_k$ is located at the beam center. The normalized antenna gain pattern $g(\theta_{b,k}), \forall k \in K_b, b \in B$, is computed as

$$g(\theta_{b,k}) = \begin{cases} 4 \left( \frac{\sin(\beta \sin(\theta_{b,k}))}{\sin(\beta \sin(\theta_{b,k}))} \right)^2, & \text{if } 0 < \theta_{b,k} \leq \frac{\pi}{2}, \\ 1, & \text{if } \theta_{b,k} = 0, \end{cases}$$

where $\beta$ is the radius of the antenna’s circular aperture, $\lambda$ is the carrier wavelength, and $J_1(\cdot)$ is the first kind Bessel function of the order one. The Doppler shifts caused by the satellite mobility is assumed to be perfectly compensated by using proper estimation techniques [13]. Fig. 2 shows an example of the normalized beam pattern with the aperture radius $\beta = 5\lambda$.

It explicitly unveils that the main energy is concentrated on the main lobe of each beam, which gives hints to locate the satellite beams hereafter. After that, the statistical channel gain (SCG) at an arbitrary UE$_k$, denoted by $G_{b,k}$, is defined as

$$G_{b,k} = \frac{G_{\text{rx},b,k} g_{b,k}}{L_{\text{fs},b,k} L_{\text{atm}}}, \forall k \in K_b, b \in B,$$

where $L_{\text{fs},b,k}$ denotes the free space path loss, which is

$$L_{\text{fs},b,k} = \frac{16\pi^2 S_{b,k}^4}{\lambda^2}, \forall k \in K_b, b \in B,$$

where $S_{b,k}$ denotes the slant range (line-of-sight distance along a slant direction) between the satellite and UE$_k$ in the $b$-th beam. The received antenna power gain $G_{\text{rx},b,k}$ is [12]

$$G_{\text{rx},b,k} = \epsilon_{b,k} \pi^2 d^2 / \lambda^2, \forall k \in K_b, b \in B,$$

where $\epsilon_{b,k}$ is the antenna efficiency at UE$_k$ in the $b$-th beam and $d$ is the satellite antenna diameter. We assume the network is in a noise-limited scenario, where a proper bandwidth allocation has been performed to avoid harmful levels of inter-beam interference [14]. The received carrier-to-noise ratio (CNR) at UE$_k$ served by beam $b$ is $CN_{b,k} = \rho_{b,k} G_{\text{rx},b,k}/\sigma^2_k$, where $\sigma^2_k$ denoted the noise variance at UE$_k$ and $\rho_{b,k}$ is the transmit power from $b$-th beam to UE$_k$. In the $b$-th satellite beam, the total gain at UE$_k$ through the space environment is a complicated expression of the practical aspects in multi-beam satellite communications comprising the beam pattern, effective transmitted and received antenna gains, free space path loss, and atmospheric loss. Several parameters, such as $g(\theta_{b,k})$ defined in (3) and $G_{\text{rx},b,k}$ defined in (6), display the influences of hardware configurations from a specific reflector antenna with a circular aperture. Besides, the environmental parameters depending on the satellite beam locations, which are mathematically formulated in (2)-(6), are of interest to design for the good link budget.

III. JOINT BEAM PLACEMENT AND LOAD BALANCING OPTIMIZATION

This section formulates and solves a beam placement problem balancing the active beams and the effective gains.

A. Problem Statement

As analyzed in the previous section, the statistical channel gains are designable parameters, which are obtained by optimizing the beam centers. For such, let us introduce $\bar{o}_b = [\phi_b, \theta_b]^T$ and $o_{b,k} = [\phi_{b,k}, \theta_{b,k}]^T$ as the coordinate of the $b$-th beam’s center and its served UE$_k$, respectively. Here $\phi$ and $\theta$ stand for the corresponding longitude and latitude. We assume that all considered positions have the same elevation (e.g., set to zero for the sake of simplicity). Let us denote $\bar{d}(o_{b,k}, \bar{o}_b)$ the geography distance between the two coordinates, which is computed by the spherical law of cosines as $\bar{d}(o_{b,k}, \bar{o}_b) = R \arccos(\tilde{d}_{b,k})$, where $R$ is the Earth’s radius and $\tilde{d}_{b,k}$ is defined as follows $\tilde{d}_{b,k} = \sin(\phi_{b,k}) \sin(\phi_b) + \cos(\phi_{b,k}) \cos(\phi_b) \cos(\theta_{b,k})$.
\[
\cos(\phi_{b,k}) \cos(\phi_b) \cos(\Delta \theta_{b,k}), \quad \text{with } \Delta \theta_{b,k} = \theta_{b,k} - \theta_b, \ \forall k \in K_b \text{ and } b \in B.
\]

We aim at minimizing a utility function that balances the number of beams operating at the satellite while attempting to push all users close to the beam centers as follows:

\[
\begin{align*}
\text{minimize} & \quad w_1 \sum_{b \in B} \sum_{k \in K_b} \tilde{d}(o_{b,k}, o_b)^2 + w_2 |B| \quad (7a) \\
\text{subject to} & \quad g_{b,k} \geq g^{\max}/2, \ \forall b \in B, k \in K_b, \quad (7b) \\
& \quad K_b \neq \emptyset, K_b \subseteq K, \ \forall b \in B, \quad (7c) \\
& \quad K_b \cap K_b = \emptyset, \ \forall b, b' \in B, \quad (7d) \\
& \quad \bigcup_{b=1}^{|B|} K_b = K, \quad (7e)
\end{align*}
\]

where the non-negative weights \(w_1, w_2 \geq 0\) satisfy \(w_1 + w_2 = 1\), and respectively represent the different priorities to the objective function of problem (7). The weights \(w_1\) and \(w_2\) are flexibly designed to handle the conflicting metrics. Specifically, we stress that the former ensures that each user is located as close to its satellite beam center as possible, while minimizing the number of beams allows allocating more power to each satellite beam conditioned on the fixed power budget. The constraints (7b) ensure that each user is located in at least the half-power-bandwidth of its served beam, which is motivated by Fig. 2, where users should be laid in the main lobe of the beam. The constraints (7c) and (7d) imply that each user is only served by a single beam, and each active beam must involve at least one user for energy efficiency conditioned on the limited power budget at the satellite. Furthermore, constraint (7e) guarantees that all users are in the coverage area of the satellite. Problem (7) is a mixed-integer non-convex program due to the inherent non-convexity of the objective function and the constraints (7a).

A discrete feasible domain (7c)-(7e) makes problem (7) NP-hard and it may require an extremely high cost to find the global optimum. Hence, a heuristic algorithm can obtain an efficient sub-optimal solution with finite time consumption. The combinatorial structure might result in multiple solutions to (7), so the unbalanced load issue can be mitigated by a solution that mostly spreads out users across the active beams.

\section*{B. Define the Number of Active Beams}

To shed the light on finding a minimal number of active beams, we consider a circular pattern of the \(b\)-th beam as shown in Fig. 3(a) with the half power bandwidth defined by the angle \(2\psi, \ \forall b \in B\). Based on the constraints (7b), the \(b\)-th beam will serve users in its HPBW and HPBW, and the served user set \(K_b\) can be defined by verifying the angles among all the users. In more detail, the angle \(\psi_{k,\ell}\) between two users \(k\) and \(\ell\), with \(k, \ell \in K_b\), seen from the satellite should hold that \(\psi_{k,\ell} \leq \tilde{\psi}\), \(k, \ell \in K_b, \ \forall b \in B\). Using HPBW \(2\tilde{\psi}\) as in [9], [15] may result in some users not to be covered. Instead, we use the quantity \(\bar{\psi}\) to guarantee that all users in the same beam are in the HPBW area of the satellite’s beams. Therefore, to define the minimal number of active beams, we propose to solve the following optimization problem

\[
\begin{align*}
\text{minimize} & \quad |B| \quad (8a) \\
\text{subject to} & \quad \psi_{k,\ell} \leq \bar{\psi}, \ \forall k, \ell \in K_b, \ \forall b \in B, \quad (8b) \\
& \quad (7c)-(7e). \quad (8c)
\end{align*}
\]

Despite the simplification compared with the original problem (7), the non-convex and non-smooth properties are still preserved in problem (8). To effectively find a good feasible solution, we develop a heuristic algorithm for problem (8) based on the graph theory. In particular, a graph \(G\) is introduced with a pair \((V(G), E(G))\). The set \(V(G) = \{1, \ldots, K\}\) consists of the K vertices each related to a user. Meanwhile, the set \(E(G)\) of edges in which each edge represents a connection between two distinct vertices, i.e.,

\[
E(G) = \{\{k, \ell\} | \psi_{k,\ell} \leq \bar{\psi}, \ \forall k, \ell \in V(G)\}, \quad (9)
\]

and noticing that no two vertices are connected by more than one edge.\(^1\) From the constraints (8b), we can construct the adjacency matrix \(U \in \mathbb{R}^{K \times K}\) of graph \(G\), whose \((k, l)\)-th element, denoted by \([U]_{k,l}\), is defined as follows

\[
[U]_{k,l} = \begin{cases} 
1, & \text{if } \psi_{k,\ell} \leq \bar{\psi}, k, \ell \in K, \\
0, & \text{otherwise.}
\end{cases} \quad (10)
\]

From (10), the two vertices \(k\) and \(\ell\) are adjacent if \([U]_{k,l} = 1\) meaning that there is an edge between them. One feature of graph \(G\) can be observed in Theorem 1.

\textbf{Theorem 1.} From the HPBW criterion defining the edges in (9), if each active beam serves at least \(\lceil (K - 1)/2 \rceil\) users where \(\lceil \cdot \rceil\) is the ceiling function, the graph \(G\) is connected.\(^2\) The number of active beams is lower bounded by \(|B| \geq \lceil K/\lceil (K - 1)/2 \rceil \rceil\).

\textbf{Proof.} The proof is to show that the neighborhoods of vertices are overlapping and is omitted due to space limitations. \(\square\)

\(^1\) Even though the graph \(G\) may be disconnected in practice, this theorem establishes a necessary condition so that each

\(^2\) In our considered framework, \(G\) should be an undirected graph, that is, \(\{k, \ell\} \in E(G)\) is equivalent to \(\{\ell, k\} \in E(G)\).
active beam can serve multiple users when they are not quite distant from each other based on the HPBW. We can provide a lower bound on the number of active beams as the graph $G$ is connected. The network can place the beam centers effectively by the following important property.

**Lemma 1.** If multiple users belong to the same beam, they formulate a clique in which the vertices are mutually adjacent.

**Proof.** The proof is accomplished by using the properties in (9) and (10), which is omitted due to space limitations □

In Lemma 1, each clique is a subset of vertices that usually consists of more than three users. Subsets including one or two users per beam are also called cliques for the sake of convenience. It provides an effective hint to place the beam center based on the half power bandwidth, which links to a clique of the graph $G$. The main idea to solve problem (8) is that if each clique contains more vertices, the less number of active beams needs to serve all the users.

Our proposed approach is summarized in the first stage of Algorithm 1. It starts with formulating the graph $G$ with the sets of vertices $V(G)$ and edges $E(G)$ for the satellite and user’s locations by using (9). After that, we can compute the adjacency matrix $U \in \mathbb{R}^{K \times K}$ as shown in (10). Let us denote $\mathcal{H}_i = \{X_{b,i}\}_{b \in B}$ the subset comprising of cliques $X_{b,i}$ with the same number of edges, e.g., $\mathcal{H}_1$ includes the cliques with single edge and so on. Here, the index $i = 1, \ldots, i_{\text{max}}$ stands for the number of edges in a clique. Here, $i_{\text{max}}$ is the maximum number of edges in a clique. Next, we introduce $\tilde{K} = \{\mathcal{K}(\kappa)\}$ the dictionary that contains all possibilities to the solution of problem (8), each denoted as $\tilde{K}(\kappa)$. At the beginning, $\tilde{K}$ is initially set to be empty. As aforementioned, the combinatorial structure may result in multiple solutions to problem (8). Consequently, Algorithm 1 must scrutinize many available combinations in an iterative manner to find the minimum number of active beams to serve all the users. Alternatively, the number of solutions $\{\tilde{K}(\kappa)\}$ will be gradually expanded along with iterations. The iterative approach starts scanning $H_{i_{\text{max}}}$ to define $\{\tilde{K}(\kappa)\}$, each formulated as

$$\tilde{K}(\kappa) = \{X_{b,i_{\text{max}}}, X_{b,i_{\text{max}}} \cap X_{b',i_{\text{max}}} = \emptyset, \forall X_{b,i_{\text{max}}, X_{b',i_{\text{max}}} \subseteq H_{i_{\text{max}}}}\}, \forall \kappa.$$  

(11)

After that, the dictionary $\tilde{K}$ will be updated by scrutinizing all the remaining subsets $\{\mathcal{H}_i\} \setminus H_{i_{\text{max}}}$. The subset $\mathcal{H}_{i_{\text{max}}}$ is investigated at iteration $i$ and the dictionary is expanded as

$$\tilde{K}(\kappa) \leftarrow \tilde{K}(\kappa) \cup \{X_{b,i}\}, \forall \kappa,$$

(12)

where the following definition holds

$$X_{b,i_{\text{max}}-i} = \{X_{b,i_{\text{max}}-i} \cap X_{b',i_{\text{max}}-i} = \emptyset, \forall X_{b,i_{\text{max}}-i}, X_{b',i_{\text{max}}-i} \subseteq H_{i_{\text{max}}-i}, X_{b,i_{\text{max}}-i} \cap \tilde{K}(\kappa) = \emptyset\}. $$

Even though the dictionary update in (12) may lead to a local solution to problem (8), the condition $X_{b,i_{\text{max}}-i} \cap \tilde{K}(\kappa) = \emptyset$ truncates many cliques that makes our proposed approach have the total cost significantly lower than an exhaustive search. After scrutinizing through all the subsets $\mathcal{H}_i, \forall i$, or all users allocated, the optimized solution $\{\mathcal{K}_b\}$ is then selected from all the possible solutions in $\tilde{K}$ as

$$\mathcal{K}_b = \arg\min_{\kappa \in \mathcal{K}} |\mathcal{K}(\kappa)|.$$  

(13)

We notice that once $\{\mathcal{K}_b\}$ is obtained, the beam center of the $b$-th beam, $\forall b \in B$, can be computed as

$$\mathcal{O}_b = \frac{1}{|\mathcal{K}_b|} \sum_{k=1}^{|\mathcal{K}_b|} \mathcal{O}_{b,k}, \forall b \in B.$$  

(14)

For the sake of the clarity, one toy example presenting a realization of users’ location for a multi-beam satellite system serving 10 users is given as follows.

**Example 1.** We consider a MEO satellite system where the parameter setting is given in Section IV. On the ground, there are 10 users with their locations illustrated in Fig. 3(b). Users whom the same beam can serve are represented by a link between the two corresponding locations. By utilizing (9) with $2\psi = 3.2^\circ$ [16], we can construct a graph $G$ as shown in Fig. 3(b) comprising $V(G) = \{1, \ldots, 10\}$ and $E(G) = \{(k, l) : |\psi_{k,l} - \psi_{k,l}^*| \leq 1^\circ, k, l \in V(G)\}$. Subsequently, the adjacency matrix is formulated as

$$U = \begin{bmatrix}
1 & 0 & 1 & 1 & 1 & 0 & 1 & 0 & 0 & 0 \\
0 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 0 \\
1 & 1 & 1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\
1 & 0 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \\
1 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1
\end{bmatrix}.$$  

(15)

Utilizing the adjacency matrix in (15) and the undirected property, all possible cliques can be synthesized as

$$\mathcal{H}_1 = \{(1), (2), (3), (4), (5), (6), (7), (8), (9), (10)\},$$  

(16)

$$\mathcal{H}_2 = \{(1, 3), (1, 4), (1, 5), (1, 7), (1, 8), (2, 3), (2, 8), (2, 10)\},$$  

(17)

$$\mathcal{H}_3 = \{(3, 4), (3, 6), (4, 5), (4, 9), (5, 7), (6, 8), (8, 10)\},$$  

(18)

From the cliques with the 3 edges involved in $\mathcal{H}_3$, the following cliques can coexist

$$\mathcal{K}_1 = \{(2, 8, 10), (1, 3, 4)\},$$  

(19)

$$\mathcal{K}_2 = \{(2, 8, 10), (1, 4, 5)\},$$  

(20)

$$\mathcal{K}_3 = \{(2, 8, 10), (1, 5, 7)\},$$  

(21)

which indicate that the cliques should be non-overlapping to fulfill the constraints (7d). We further expand $\mathcal{K}(\kappa), \kappa \in \{1, 2, 3\}$ by adding the cliques with the 2 edges in (17) and update $\{\mathcal{K}(\kappa)\}$ to obtain the solutions. More specifically, $\mathcal{K}^{(1)} = \mathcal{K}^{(1)} \cup \{(5, 7)\}$, $\mathcal{K}^{(2)} = \mathcal{K}^{(2)} \cup \{(3, 6)\}$, and $\mathcal{K}^{(3)} = \mathcal{K}^{(3)} \cup \{(3, 6)\}$, which result in

$$\mathcal{K}^{(1)} = \{(2, 8, 10), (1, 3, 4), (5, 7)\},$$  

(22)

$$\mathcal{K}^{(2)} = \{(2, 8, 10), (1, 4, 5), (3, 6)\},$$  

(23)

$$\mathcal{K}^{(3)} = \{(2, 8, 10), (1, 5, 7), (3, 6), (4, 9)\}.$$  

(24)
Mathematically, we solve the following optimization problem by utilizing Lemma 1.

1. **Stage 1: Define the number of active beams**
   - Formulate graph $G$ with a pair $(V(G), E(G))$ and compute the adjacency matrix $U$ as in (10).
   - Compute all possible cliques $\mathcal{H}_i = \{\tilde{x}_{b, i}\}$ from graph $G$.
   - Initial $\{\hat{K}^{(0)}\}$
   - For each group set $\mathcal{H}_i$ in $\mathcal{H}$ do
     - if $|\hat{K}^{(\kappa)}| < K$ then
       - Update $\tilde{K}^{(\kappa)}$ as in (12).
   - end if
2. **Stage 2: Refine the beam centers**
   - Transform all user locations $\{\mu_k\}$ to the Cartesian coordinates by utilizing $x = R \cos(\phi) \cos(\theta)$, $y = R \cos(\phi) \sin(\theta)$, and $z = R \sin(\phi)$.
   - Perform the K-means clustering to problem (30).
   - while any $U_{b,k} \neq 1, \forall k, \ell \in \mathcal{K}_b$
   - Transform all the beam centers $\{\mu_k\}$ to the geographic coordinates as $\phi = \arcsin(z/R)$ and $\theta = \arctan(y/x)$.
3. **OUTPUT:** The user sets $\{K^*_b\}$ and the number of active beams $|\hat{K}|$.

Finally, $\tilde{K}^{(\kappa)}$, $\kappa \in \{1, 2, 3\}$, are expanded by utilizing $\mathcal{H}_i$ as $\tilde{K}^{(1)} = \hat{K}^{(1)} \cup \{(6), (9)\}$, $\tilde{K}^{(2)} = \hat{K}^{(2)} \cup \{(7), (9)\}$, and $\tilde{K}^{(3)} = \hat{K}^{(3)}$, which result in

$\tilde{K}^{(1)} = \{(2, 8, 10), (1, 3, 4), (5, 7), (6), (9)\}$,
$\tilde{K}^{(2)} = \{(2, 8, 10), (1, 4, 5), (3, 6), (7), (9)\}$,
$\tilde{K}^{(3)} = \{(2, 8, 10), (1, 5, 7), (3, 6), (4, 9)\}.$

Using (13), the last solution including the minimum number of set, i.e., $\{K^*_b\} = \tilde{K}^{(3)} = \{(2, 8, 10), (1, 5, 7), (3, 6), (4, 9)\}$. Therefore, the network of active beams should be $|\hat{K}| = 4$.

C. Refine the solution with K-means clustering

By applying the first stage, the number of active beams has been obtained with a guarantee that users are in the HPBW of each beam. The main drawback of this stage is that this stage has focused on maximizing the number of users in one beam, which might cause an unbalanced load among the beams. As a result, some active beams need to serve many users, while the remaining is in a sparse situation with a few users. For a fairness level with a balanced load among the active beams, our goal is to minimize the distance from every user to its beam center targeting at a homogeneous network. Mathematically, we solve the following optimization problem

\[
	ext{minimize} \quad \sum_{b \in B} \sum_{k \in \mathcal{K}_b} d(\mu_{b,k}, \hat{o}_b) \quad \text{(28a)}
\]

subject to \quad \text{(7b) – (7e)}. \quad \text{(28b)}

In order for the network to handle problem (28), a special mechanism should be applied for the geographic coordinates. In particular, we convert each geographic coordinate denoted by the longitude and latitude of the corresponding Cartesian coordinate denoted by $(x, y, z)$ by exploiting the following relationship $x = R \cos(\phi) \cos(\theta)$, $y = R \cos(\phi) \sin(\theta)$, and $z = R \sin(\phi)$. Hence, the Cartesian coordinates $\hat{o}_{b,k}$ are obtained for all the users and the beam center of the $b$-th beam by utilizing $\hat{o}_{b,k}$ and $\hat{o}_b, \forall b, k$, respectively. Next, problem (28) is reformulated as

\[
\text{minimize} \quad \sum_{b \in B} \sum_{k \in \mathcal{K}_b} \|\hat{o}_{b,k} - \hat{o}_b\|^2 \quad \text{(29a)}
\]

subject to \quad \text{(7b) – (7e)}, \quad \text{(29b)}

where $\|\cdot\|$ is the Euclidean norm. By neglecting the constraints (7b), problem (29) is aligned with the standard form of the K-means clustering as

\[
\text{minimize} \quad \sum_{b \in B} \sum_{k \in \mathcal{K}_b} \|\hat{o}_{b,k} - \tilde{o}_b\|^2 \quad \text{(30a)}
\]

subject to \quad \text{(7c) – (7e)}, \quad \text{(30b)}

and therefore the optimal solution to $\{K^*_b\}$ and $\{\tilde{o}_b\}$ can be obtained in polynomial time. Let us denote $\{\hat{o}_b\}$ the optimal solution to the beam centers, we can reverse the optimal geographic coordinates. Noting that a Cartesian coordinate $(x, y, z)$, the corresponding geographic coordinate $(\phi, \theta)$ is mathematically computed as $\phi = \arcsin(z/R)$ and $\theta = \arctan(y/x)$. Since the relaxed problem (30) does not guarantee the HPBW requirements, we may need to perform the K-means clustering approach several times. The beam centers and users per beam are refined based on the K-means clustering, which is summarized in the second stage as shown in Algorithm 1. The proposed algorithm combines the benefits of both the aforementioned stages by efficiently solving problem (7) in a hierarchical fashion.

IV. NUMERICAL RESULTS

The considered beam placement framework is testified by a MEO satellite serving simultaneously multiple users randomly located in an area with latitude and longitude within the ranges $[-120, -110]$ and $[0^\circ, -88.7^\circ]$ and its altitude is $8063$ [km]. The total transmit power at the satellite is $23.5$ [dBW]. The carrier frequency is $18.05$ [GHz] and the aperture radius is $5\lambda$ with $\lambda$ being the wavelength. The satellite antenna diameter is $0.6$ [m], while the maximum gain at each beam center is $50$ [dB] and HPBW $2\psi = 3.2^\circ$ [16]. The noise variance is $-118$ [dBW].

Fig. 4(a) considers a network with 20 users and plot the cumulative distribution function (CDF) of the channel gain to noise ratio (SCGNR) [dBi] for each user, i.e., $10 \log_{10}(G_{b,k}/\sigma_b^2)$, $\forall b, k$. Both the average and minimum SCGNR of the users by exploiting Stage 1 only or the two-stage algorithm (Algorithm 1). The results show that the two stages bring benefits to both the average and min SCGNRs. Fig 4(b) displays the load balancing gap between beams as a
The proposed beam placement and load balancing solution inherits the benefits of unsupervised learning from K-means clustering. Numerical results showed good channel gains by inheriting the benefits of unsupervised learning from K-means clustering. The second stage balances the load among the active beams by utilizing Stage 1, thereby offering a smaller load balancing gap than by only utilizing Stage 1.

The link budget, i.e., the received carrier-to-noise ratio (CNR) per user, is illustrated in Table I for the different benchmarks. Specifically, the performance of Algorithm 1 is compared with the two previous benchmarks: i) Beam Aperture that was used in [9, Algorithm 1] based the angular separation between users and the beam aperture angle. Notice that this benchmark focuses on the beam placement only; and ii) Homo. Balance where nearest users are grouped together and served by the same beam. This idea was brought from the nearest user selection in terrestrial communications such as [17] and more focusing on the load balancing. Slight decreases of both the min CNR and average CNR per user are observed for all three algorithms as the number of users increases. However, Algorithm 1 always achieves the best performance among the benchmarks.

V. CONCLUSION

This paper has demonstrated the critical role of beam placement optimization in order to offer good channel gains to all the available users in the coverage area. We proposed an approximate solution to the non-convex optimization problem and obtained a good feasible solution in polynomial time by a two-stage algorithm. The first stage defines the minimal number of active beams based on the graph theory. Meanwhile, the second stage balances the load among the active beams by inheriting the benefits of unsupervised learning from K-means clustering. Numerical results showed good channel gains by the proposed beam placement and load balancing solution.

TABLE I

| Ben./CNR          | No. of users | 10 | 15 | 20 | 25 |
|-------------------|--------------|----|----|----|----|
| Beam Aperture     | Min CNR [dB] | 18.98 | 18.15 | 17.54 | 17.09 |
|                   | Avg. CNR [dB] | 19.09 | 18.28 | 17.69 | 17.25 |
| Homo. Balance     | Min CNR [dB] | 19.97 | 19.08 | 18.64 | 18.27 |
|                   | Avg. CNR [dB] | 20.44 | 19.68 | 19.25 | 18.98 |
| Algorithm 1       | Min CNR [dB] | 20.36 | 19.58 | 19.12 | 18.85 |
|                   | Avg. CNR [dB] | 20.52 | 19.76 | 19.32 | 19.05 |

Fig. 4. The system performance: (a) plots CDF of the SCGNR [dB] per user; and (b) plots load balancing gap versus the total number of users.
