We study a quantum thermal engine model for which the heat transfer law is determined by Ein-
stein’s theory of radiation. The working substance of the quantum engine is assumed to be a two-
level quantum systems of which the constituent particles obey Maxwell-Boltzmann(M.B.), Fermi-
Dirac(F.D.) or Bose-einstein(B.E.) distributions respectively at equilibrium. The thermal efficiency and
its bounds at maximum power of these models are derived and discussed in the long and short ther-
mal contact time limits. The similarity and difference between these models are discussed. We also
can compare the efficiency bounds of this quantum thermal engine to those of its classical counterpart.

INTRODUCTION

The Carnot engine plays a crucial role in the founda-
tions of thermodynamics. However, it can not be real-
ized in practice since its output power is infinitesimally
small due to its reversibility. Real thermal engines can
not work as slowly as Carnot engines to preserve equi-
librium and must lose energy during the working cycles
due to various reasons. This makes the efficiency of real
thermal engines below that of an ideal Carnot engine.
To optimize the thermal engines in the real world, a lot
of “realistic” models have been established and studied
in the literature[1–8]. One of the most practical problem
associated with the optimization of real heat engines is
its efficiency at maximum power. This problem was
firstly studied by Curzon and Ahlborn in 1975[1]. For
Carnot-like heat engines, the authors assumed that the
temperature differences between the heat reservoirs and
working substance are finite and fixed, thus the two heat
transferring processes are not reversible anymore, while
the adiabatic expansion and compression processes are
still reversible. Under these assumptions, they derived
the well-known CA efficiency \( \eta_{CA} = 1 - \sqrt{T_c/T_h} \), where
\( T_h \) and \( T_c \) are the temperatures of the hot and cold heat
reservoirs with which the working substance is in con-
tact. Though the CA formula has a good agreement
with measured efficiencies of some thermal plants, this
model still has some intrinsic drawbacks. On one hand,
it gives neither an exact nor constraint result for the ef-
ficiency as pointed out by Ref.[4]. On the other hand,
in real world situations the temperature differences be-
tween the working medium and heat reservoirs are not
constant and the heat transferring process could be gov-
erned by some more general physical laws which can
incorporate temperature changing during heat transfer-
ring processes.

In our previous work on classical engines[8], we have
seen that the heat transfer law plays a crucial role on
the efficiency at maximum power problem. For Carnot
engines, the time periods for which the adiabatic expan-
sion and compression processes last are usually negligi-
ably short, while those of the two isothermal heat trans-
ferring processes are infinitely long, therefore Carnot en-
gines have zero output power. In real world situations,
the isothermal heat transferring processes must last for a
finite period of time and obey specific heat transferring
laws. In Ref.[8], we studied a thermal engine model for
which Newton’s cooling law is obeyed during the heat
transferring processes, and derived the upper and lower
bounds for the efficiency at maximum power in the long
and short contact time limits respectively. By consid-
ering the heat transferring processes during which the
temperature of the working medium is close to or far
from isothermal, and adjusting the ratio between the
heat capacities of the heating and cooling stages, the
model can simulate different types of engines including
but not limited to Carnot engines.

The studies of classical thermal engines can be gener-
alized to their quantum counterparts. Recently, differ-
ent models of quantum thermal engines are extensively
studied in the literature[9–11]. The efficiency of a quan-
tum thermal engine at maximum power has also been
studied in Ref.[12], where the quantum thermal engine
is based on the model discussed in Ref.[13], in which the
quantum thermal engine is composed of particles con-
ained in a one-dimensional (1D) infinite potential well,
and the wall of the well can expand to perform work.
The derived efficiency at maximum power is a univer-
sal number.

Following the same spirit, we try to generalize our
previous work to the quantum world. For simplicity
and without losing generality, the working substance in our model of thermal engines is a two-level quantum system, which can be chosen as the lowest two levels of a 1D infinite quantum well or a 1D harmonic oscillator. Unlike the discussion in Ref.[13], the temperature rather than average energy is used to describe the thermal equilibrium state as in Ref.[2]. What is important here is that the heat transferring process between the working substance and the heat reservoir is described by Einstein’s theory of radiation. This can be thought as the quantum version of the model discussed in Ref.[8] in some way. For simplicity, we denote this kind of quantum thermal engine by “quantum Einstein engine”. We are interested in the efficiency and its bounds at maximum power.

The organization of the paper is as follows. We first study the quantum thermal engine of which the constituent particles of the working substance obey the M.B.(Maxwell-Boltzmann) distribution. This will shed light on our successive studies on the other two models. For this model, we derive the heat transferring law based on Einstein’s theory of radiation, and give the formulas of the heat transfer and entropy production. As in Ref.[8], we study the efficiency at maximum power and its bounds in the long and short contact time limits. We also study quantum engines for which F.D.(Fermi-Dirac) and B.E.(Bose-Einstein) distributions are applied.

QUANTUM EINSTEIN ENGINE ASSOCIATED WITH M.B. DISTRIBUTION

General results for heat transfer and entropy production

The working substance of our quantum thermal engine is assumed to be a two-level quantum system with energy levels \( E_1 \) (low) and \( E_2 \) (high). The energy difference of the two levels is \( E_2 - E_1 = \hbar \nu \), where \( \hbar \) is the Planck’s constant. The particle numbers at low and high energy levels are \( N_1 \) and \( N_2 \) respectively, and the fixed total particle number is given by \( N_0 = N_1 + N_2 \). For simplicity, we first consider the case that the constituent particles of the quantum system satisfy M.B. distribution at equilibrium states. Assume the initial temperature of the system is \( T_1 \), then the initial particle distributions are

\[
N_1 = N_0 \frac{1}{1 + \exp (-\beta_1 \hbar \nu)} \quad N_2 = N_0 \frac{1}{1 + \exp (\beta_1 \hbar \nu)}, \tag{1}
\]

where \( \beta_1 = 1/k_B T_1 \) and \( k_B \) is the Boltzmann constant. In our model of quantum thermal engine, the heat reservoir can be thought of as a black-body source with temperature \( T_2 \). When the working substance or the two-level quantum system is “in contact with” a black-body source, the heat is transferred by the photon emission and absorption. This heat transferring process is described by Einstein’s theory of radiation

\[
\frac{dN_2}{dt} = -\frac{dN_1}{dt}
= BN_0 u_\nu - 2BN_2 u_\nu - AN_2 = -aN_2 + b, \tag{2}
\]

where \( a = 2B u_\nu + A \), \( b = BN_0 u_\nu \). \( A \) and \( B \) are the famous Einstein’s coefficients, and \( u_\nu \) is the spectral energy density of the black-body source. The solution of Eq.(2) is given by

\[
N_2(t) = \frac{b}{a} - \left[ \frac{b}{a} - N_2(0) \right] \exp (-at) \tag{3}
\]

Introducing the distribution function \( f(\beta) = 1/(1 + \exp (\beta \hbar \nu)) \) for level \( E_2 \), then we have

\[
N_2(0) = N_0 f(\beta_1), \quad N_2(t \to \infty) = \frac{b}{a} = N_0 f(\beta_2). \tag{4}
\]

At time \( t \), we have \( N_2(t) = f(\beta(t)) N_0 \) where

\[
f(\beta(t)) = f(\beta_2) - [f(\beta_2) - f(\beta_1)] \exp (-at). \tag{5}
\]

Similarly, for level \( E_1 \), we have \( N_1(t) = (1 - f(\beta(t))) N_0 \). We are interested in the situation with \( \beta \hbar \nu \ll 1 \), which is true if the size of the quantum well is not too small or the spring constant of the harmonic oscillator is not too large at high temperature. To the leading order of \( \beta \hbar \nu \) we get

\[
f(\beta) \approx \frac{1}{2} - \frac{1}{4} \beta \hbar \nu, \quad a = A \coth (\beta_2 \hbar \nu / 2) \approx \frac{2A}{\beta_2 \hbar \nu}. \tag{6}
\]

Therefore, Eq.(5) leads to the changing of inverse temperature

\[
\beta(t) = \beta_2 - (\beta_2 - \beta_1) \exp \left[ -\frac{2At}{\hbar \nu \beta_2} \right]. \tag{7}
\]

It is interesting to notice that the time constant \( 1/a \) depends on the temperature of the heat reservoir. If temperature is higher, less time is needed for the working substance to reach equilibrium with the heat reservoir, this phenomenon is counterintuitive as shown by Figure[1]. Note that in general Einstein’s coefficient \( A \propto \nu^2 \), then the inverse time constant \( a \) is in fact proportional to \( \nu \). Therefore the higher the energy difference \( \hbar \nu \), the longer the time is needed for the system to reach the equilibrium state.

In terms of the distribution function \( f(\beta) \), the quantum entropy of the two-level system can be expressed as

\[
S = -k [f(\beta) \ln f(\beta) + (1 - f(\beta)) \ln (1 - f(\beta))]. \tag{8}
\]

Plug in the expression of \( f(\beta) \), and expand Eq.(8) in series of \( \beta \hbar \nu \)

\[
S = k \ln 2 - \frac{1}{8} k(\beta \hbar \nu)^2 + O(\beta \hbar \nu)^4. \tag{9}
\]
For a heat transferring process between the initial state with inverse temperature \( \beta_0 \) and the final state with inverse temperature \( \beta(t) \) at time \( t \), the heat transfer and entropy production are given by

\[
\begin{align*}
\Delta Q(t) & = (N_2(t) - N_0)h\nu = N_0h\nu(f(\beta(t)) - f(\beta_0)) \\
& = \frac{1}{4}N_0h^2\nu^2(\beta_0 - \beta(t)) + \mathcal{O}(\beta h\nu)^3, \\
\Delta S(t) & = \frac{1}{8k}h^2\nu^2(\beta_0^2 - \beta(t)^2) + \mathcal{O}(\beta h\nu)^4, \\
\end{align*}
\]

where \( N_0 \) and \( N_2(t) \) are the particle numbers of initial and final state respectively. In the derivation of \( \Delta Q(t) \), we have used the fact \( dN_2 = -dN_1 \). Generically, the energy levels of the quantum working substance during the heating and cooling stages are different since the engine must expand to perform work between the two stages. We assume that the frequencies associated with the heating and cooling stages are \( \nu_h \) and \( \nu_c \) respectively, and the initial and final inverse temperatures are \( \beta_0, \beta_h(t) \) and \( \beta_c, \beta(c) \) respectively. Therefore, to the leading order of \( \beta h\nu \), the heat transfer and entropy production during the heating stage are given by

\[
\begin{align*}
\Delta Q_h(t) & = \frac{1}{4}N_0h^2\nu^2(\beta_0 - \beta_h(t)), \\
\Delta S_h(t) & = \frac{1}{8k}h^2\nu^2(\beta_0^2 - \beta_h(t)^2). \\
\end{align*}
\]

Similarly, during the cooling stage we have

\[
\begin{align*}
\Delta Q_c(t) & = \frac{1}{4}N_0h^2\nu^2(\beta_c - \beta_c(t)), \\
\Delta S_c(t) & = \frac{1}{8k}h^2\nu^2(\beta_c^2 - \beta_c(t)^2). \\
\end{align*}
\]

We assume the time duration that the heating and cooling stages last are \( \tau_h \) and \( \tau_c \) respectively. When the quantum engine finishes a full thermodynamical cycle, the working medium returns back to its initial state and we have \( \Delta S_h(\tau_h) + \Delta S_c(\tau_c) = 0 \). The power output and the efficiency of the thermal engine are given by

\[
\begin{align*}
P & = \frac{\Delta Q_h(\tau_h) + \Delta Q_c(\tau_c)}{\tau_h + \tau_c}, \\
\eta & = 1 + \frac{\Delta Q_c(\tau_c)}{\Delta Q_h(\tau_h)}. \\
\end{align*}
\]

Here we adopt the convention that \( Q > 0(\leq 0) \) means absorbing(releasing) heat. As mentioned before, the working substance of the quantum engine under consideration is composed by particles at the two lowest levels of a 1D infinite quantum well or 1D harmonic oscillator. The cycles of the quantum engine are as follows. 1) The system absorbs heat \( Q_h \) from the hot reservoir during the time period \( \tau_h \). 2) The system expands to perform work. In case of 1D infinite quantum well, the width of the well expands from \( L_0 \) to \( L_1 \). In case of 1D harmonic oscillator, the “width” of the harmonic potential expands while its spring constant “shrinks” from \( k_0 \) to \( k_1 \) in its parameter space. 3) The system releases heat \( Q_c \) at the cold reservoir during the time period \( \tau_c \). 4) The system returns to its original size and temperature and the working medium returns to its original state.

### Efficiency and its bounds in the long contact time limit

When the contact time is long enough, the working substance can exchange heat sufficiently with the reservoirs. In this limit, \( \tau_h, \tau_c(\beta_0h\nu, cA) \) is large, and we assume the final inverse temperatures for the two stages are \( \beta_h = \beta_h(\tau_h) \) and \( \beta_c = \beta_c(\tau_c) \). Hence the heat transfers during the two stages are

\[
\begin{align*}
\Delta Q_h = \frac{1}{4}N_0h^2\nu^2x, & \quad \Delta Q_c = -\frac{1}{4}N_0h^2\nu^2y, \\
\end{align*}
\]

where \( x = \beta_0 - \beta_h \) and \( y = \beta_c - \beta_0 \). To the leading order of \( \beta h\nu \), the constraint \( \Delta S_h + \Delta S_c = 0 \) gives

\[
\begin{align*}
\nu_h^2(2\beta_h + x)x - \nu_c^2(2\beta_c - y)y & = 0, \\
\end{align*}
\]

of which the solution is given by

\[
x = \sqrt{\frac{\beta_c^2 + \frac{1}{\gamma_c}(2\beta_c - y)y - \beta_h}{}}.
\]
where $\gamma = \nu_h/\nu_c$. Substitute Eq. (16) to the expression of the output power

$$P = \frac{1}{4} N_0 h^2 \nu_h^2 x - \nu_c^2 y$$  \hspace{1cm} (17)$$
and let $\partial P/\partial y = 0$, the only meaningful solution for $y$ is found to be

$$y = \beta_c(1 + \gamma^2) - \sqrt{\beta_c^2(1 + \gamma^2) + \beta_c^2(1 + \gamma^2)^2}$$ \hspace{1cm} (18)

Plugging $y$ into Eq. (13) we obtain the thermal efficiency at maximum power

$$\eta_m = 1 - \frac{1}{\gamma^2} \frac{y}{x}$$ \hspace{1cm} (19)

$$= 1 - \frac{\gamma^2(1 - \eta_c)}{2 - \eta_c} \sqrt{1 + \gamma^2},$$

where $\eta_c = 1 - \frac{y}{h}$ is the Carnot efficiency. If we let $\gamma$ approach 0 and $\infty$ respectively, we obtain the upper and lower bounds of $\eta_m$ as

$$\frac{\eta_c}{2} \leq \eta_m \leq \frac{\eta_c}{2 - \eta_c}.$$ \hspace{1cm} (20)

Interestingly, these bounds agree exactly with those given in Ref. [4] for classical thermal engines in the long contact time limit. However, the situation is a little different for our model of quantum thermal engines. The quantum engine, either quantum-well type or harmonic-oscillator type, must expand to perform work after absorbing heat at hot reservoir. Hence its size must increase afterwards. For a quantum-well type engine, its width $L$ will increase, while for a harmonic-oscillator type engine, its spring constant $k$ will decrease. Since the frequency is anti-proportional to $L^2$ or proportional to $\sqrt{k}$, then $\gamma = \nu_h/\nu_c$ must be larger than 1, or the lower limit of $\gamma$ is 1 rather than 0. Now we have tighter bounds for $\eta_m$

$$\frac{2 - \sqrt{4 - 4\eta_c + 2\eta_c^2}}{2 - \eta_c} \leq \eta_m \leq \frac{\eta_c}{2 - \eta_c}.$$ \hspace{1cm} (21)

The efficiency $\eta_m$ can be expanded in series of $\eta_c$ as

$$\eta_m = \frac{1}{2} \eta_c + \frac{\gamma^2}{4(1 + \gamma^2)} \eta_c^2 + O(\eta_c^3).$$ \hspace{1cm} (22)

The coefficient of the second-order term lies between 1/8 and 1/4.

**Efficiency and its bounds in the short contact time limit**

In the short time limit such that $\tau \ll 1/a$, the inverse temperature can be approximated to the second order of $a\tau$ as

$$\beta(\tau) \approx \beta_1 + (\beta_2 - \beta_1)a\tau + (\beta_1 - \beta_2)\frac{1}{2}a^2\tau^2.$$ \hspace{1cm} (23)

Implementing this approximation, the entropy productions during the two stages are given by

$$\Delta S_h = \nu_h^2[-2\beta_0(\beta_1 - \beta_0)a\tau_\tau_h - (\beta_0 - \beta_h)(2\beta_0 - \beta_h)a_0^2\tau_\tau_h^2],$$

$$\Delta S_c = \nu_c^2[-2\beta_0(\beta_1 - \beta_0)a\tau_c - (\beta_0 - \beta_c)(2\beta_0 - \beta_c)a_0^2\tau_\tau_c^2].$$ \hspace{1cm} (24)

Using the same convention as in the last subsection, the constraint $\Delta S_h + \Delta S_c = 0$ gives an equation for $x$ and $y$. Since $\beta_h,\beta_c,\tau_h,\tau_c$ is an infinitesimal quantity, we match both sides of the equation order by order of $\beta_h,\beta_c,\tau_h,\tau_c$. To the first and second order, we get

$$\gamma^2(\beta_h + x)x\frac{A_h}{h_c\nu_c\tau_h} = (\beta_c - y)\frac{A_c}{h_c\nu_c\tau_c},$$

$$\gamma^2(\beta_h + 2x)a_h^2\tau_h^2 = (\beta_c - 2y)a_c^2\tau_c^2.$$ \hspace{1cm} (25)

from which one can deduce

$$\frac{\beta_h + 2x}{x(\beta_h + x)^2} = \frac{\beta_c - 2y}{y(\beta_c - y)^2}.$$ \hspace{1cm} (26)

The key step here is to simplify the above equation and get a relatively simple relation between $x$ and $y$ as in Ref. [8], hence we can avoid messing up the physics by the mathematical complexity. We assume that the temperature difference is small relative to the temperature of the heat reservoir at each heat transferring stage. Thus, $x$ is small relative to $\beta_h$ and $y$ small to $\beta_c$. Expanding both sides of Eq. (26) to the third order of $x$ and $y$, we can derive a very simple relation between $x$ and $y$

$$\frac{y}{x} = \frac{\sqrt{\beta_h}}{\beta_c}.$$ \hspace{1cm} (27)

The heat transfers during the two heating and cooling stages are given by

$$\Delta Q_h = \frac{1}{4} N_0 h^2 \nu_h^2 x a_0 \tau_h,$$

$$\Delta Q_c = -\frac{1}{4} N_0 h^2 \nu_c^2 y a_0 \tau_c,$$ \hspace{1cm} (28)

from which the output power is given by

$$P = \frac{1}{4} N_0 h^2 \nu_h^2 x a_0 \tau_h - \nu_c^2 y a_0 \tau_c.$$ \hspace{1cm} (29)

Taking into account that the spontaneous emission coefficient $A$ satisfies $A \propto \nu^3$, except a constant the output power is evaluated as

$$P \propto \frac{(\beta_c - \gamma^2 x \beta_h/\beta_c - \beta_h - x)x}{\beta_c - \gamma^2 x \beta_h/\beta_c + \gamma(\beta_h + x)a_0^2\beta_h^2}.$$ \hspace{1cm} (30)

Solve the equation $\partial P/\partial x = 0$, and plug the only meaningful solution for $x$ into the expression of the efficiency at maximum power

$$\eta_m = 1 - \frac{\beta_h + x}{\beta_c - \gamma^2 x \beta_h/\beta_c}.$$ \hspace{1cm} (31)
In series of $\eta_c, \eta_m$ can be expanded as
\[ \eta_m = \frac{\eta_c}{2} + \frac{\gamma(2\gamma^2 + \gamma + 1)}{8(1 + \gamma^2 + \gamma^3)} \eta_c^2 + \mathcal{O}(\eta_c^3). \] (32)

Taking $\gamma = 0, \infty$, the bounds of $\eta_m$ are derived as
\[ \frac{\eta_c}{2} \leq \eta_m \leq \frac{\eta_c}{2 - \eta_c}. \] (33)

Interestingly, we obtain the same rough bounds of $\eta_m$ as in the long time contact limit. Again noting that $\gamma$ can not be smaller than 1, the finer bounds of $\eta_m$ are found to be
\[ 1 - \sqrt{1 - \eta_c} \leq \eta_m \leq \frac{\eta_c}{2 - \eta_c}. \] (34)

The coefficient of the second-order term of $\eta_m$ also lies between 1/8 and 1/4.

**QUANTUM EINSTEIN ENGINE ASSOCIATED WITH THE F.D. DISTRIBUTION**

In this section, we consider the case that the constituent particles of the working substance obey the F.D. distribution. In fact we will see that this situation will reduce to that associated with the M.B. distribution even when $\beta E_{1,2} \ll 1$ (if $\beta E_{1,2} \gg 1$, both F.D. and B.E. distributions reduce to M.B. distribution). Here we still adopt the same convention for the parameters as in the last section. For each level of the quantum system, the particle numbers of the initial state are given by
\[ N_1(0) = \frac{N_0}{1 + \frac{e^{\beta E_1 + 1}}{e^{\beta E_2 + 1}}}, \quad N_2(0) = \frac{N_0}{1 + \frac{e^{\beta E_2 + 1}}{e^{\beta E_1 + 1}}}. \] (35)

Similar to what we have done in the last section, the distribution function $f^F(\beta) = 1/(1 + \frac{e^{\beta E_2 + 1}}{e^{\beta E_1 + 1}})$ is introduced. Thus the initial number distributions are $N_1(0) = N_0(1 - f^F(\beta_1))$ and $N_2(0) = N_0f^F(\beta_1)$. When the quantum system is in contact with the hot (cold) reservoir, the heating (cooling) process is described by Einstein’s theory of radiation Eq.(2). Solve this equation, we get $N_1(t) = N_0(1 - f^F(\beta(t)))$ and $N_2(t) = N_0f^F(\beta(t))$ in which $f^F(\beta(t))$ is also expressed by Eq.(5) with $\beta(0) = \beta_1$ and $\beta(\infty) = \beta_2$. Hence the heat absorbed by the working substance at time $t$ is $\Delta Q(t) = N_0\hbar\nu(f^F(\beta(t)) - f^F(\beta(0)))$. To the leading order of $\beta\hbar\nu$ we have
\[ f^F(\beta) \approx \frac{1}{2} - \frac{1}{8}\beta\hbar\nu, \] (36)
\[ a^F = \frac{e^{\beta_2 E_2} + e^{\beta_2 E_1} + 2}{e^{\beta_2 E_2} - e^{\beta_2 E_1}} \approx \frac{4A}{\beta_2 \hbar\nu}. \] (37)

The quantum entropy of the working substance is approximated by
\[ S^F \approx \ln 2 - \frac{1}{32}\beta^2\hbar^2\nu^2. \] (38)

One can see that the expressions of $f^F(\beta), a^F$ and $S^F$ differ from their maxwellian counterparts only in the coefficients of the leading order of $\beta\hbar\nu$. If we go on carrying the calculations as before, it is not difficult to find that the results are the same as those associated with M.B. distribution. In other word, the quantum Einstein engine with fermionic working substance has no significant difference from that with the maxwellian working substance if $\beta E_{1,2} \ll 1$.

**QUANTUM EINSTEIN ENGINE ASSOCIATED WITH THE B.E. DISTRIBUTION**

**General results for heat transfer and entropy production**

Now we consider the the quantum Einstein engine of which the working substance obeys the B.E. distribution. The discussions follow quite similar steps as the previous section. The initial particle distributions of the two-level quantum systems are
\[ N_1(0) = \frac{N_0}{1 + \frac{e^{\beta E_1}}{e^{\beta E_2 + 1}}}, \quad N_2(0) = \frac{N_0}{1 + \frac{e^{\beta E_2}}{e^{\beta E_1 + 1}}}. \] (39)

The heating (cooling) process is again governed by Einstein’s theory of radiation. Introducing the distribution function $f^B(\beta) = 1/(1 + \frac{e^{\beta E_2}}{e^{\beta E_1 + 1}})$, then at time $t$ the particle distributions become $N_1(t) = N_0(1 - f^B(\beta(t)))$ and $N_2(t) = N_0f^B(\beta(t))$ with $\beta(0) = \beta_1$ and $\beta(\infty) = \beta_2$. The heat transfer is given by $\Delta Q(t) = N_0\hbar\nu(f^B(\beta(t)) - f^B(\beta(0)))$. Similarly, to the leading order of $\beta\hbar\nu$ we have
\[ a^B = \frac{e^{\beta_2 E_2} + e^{\beta_2 E_1} - 2}{e^{\beta_2 E_2} - e^{\beta_2 E_1}} \approx \frac{4A}{\beta_2 \hbar\nu}. \] (40)

The quantum entropy production is further approximated by
In what follows, we will ignore the superscript “B” for simplicity. For the heating stage, we use $E_{h0}$ and $E_h$ to denote the initial (low) and final (high) energy levels, $\beta_{h0}$ and $\beta_h(t)$ to denote the initial and final inverse temperatures. Define the frequency $\nu_h$ by $E_h - E_{h0} = h\nu_h$, then the heat transfer and entropy production during the heating and cooling stages are given by

$$\Delta Q_h(t) = \frac{1}{2} N_0 h^2 \nu_h^2 X_h (\beta_{h0} - \beta_h(t)), \quad \Delta S_h(t) = Y_{h1}(\beta_{h0} - \beta_h(t)) + Y_{h2}(\beta_{h0}^2 - \beta_h^2(t)), (42)$$

$$\Delta Q_c(t) = \frac{1}{2} N_0 h^2 \nu_c^2 X_c (\beta_{c0} - \beta_c(t)), \quad \Delta S_c(t) = Y_{c1}(\beta_{c0} - \beta_c(t)) + Y_{c2}(\beta_{c0}^2 - \beta_c^2(t)), (43)$$

where

$$X_h = \frac{E_{h0} E_h}{(E_{h0} + E_h)^2}, \quad Y_{h1} = \frac{E_h E_{h0} \ln \frac{E_{h0}}{E_h}}{2(E_h + E_{h0})^2},$$

$$Y_{h2} = \frac{E_{h0} E_h h \nu_h (3(E_h^2 - E_{h0}^2) + 2(E_{h0}^2 - 4E_{h0} E_h + E_h^2) \ln \frac{E_{h0}}{E_h})}{24(E_{h0} + E_h)^3},$$

$$X_c = \frac{E_{c0} E_c}{(E_{c0} + E_c)^2}, \quad Y_{c1} = \frac{E_c E_{c0} \ln \frac{E_{c0}}{E_c}}{2(E_c + E_{c0})^2},$$

$$Y_{c2} = \frac{E_{c0} E_h \nu_c (3(E_{h0}^2 - E_{c0}^2) + 2(E_{c0}^2 - 4E_{c0} E_h + E_h^2) \ln \frac{E_{h0}}{E_h})}{24(E_{c0} + E_c)^3}.$$

**Efficiency and its bounds in the long contact time limit**

From now on, the discussions are simply parallel to what we have done in the last section. We briefly outline our results here. In this limit, $\tau_{h,c} \to \infty$. As previously did, we assume $\beta_h(\gamma_h) = \beta_h, \beta_c(\tau_c) = \beta_c, \beta_{h0} - \beta_h = x$ and $\beta_{c0} - \beta_c = -y$. From $\Delta S_h + \Delta S_c = 0$ we have

$$Y_{h1}x + Y_{h2}(2\beta_h + x)x - Y_{c1}y - Y_{c2}(2\beta_c - y)y = 0. (45)$$

Solve this equation, we have

$$x = \sqrt{\frac{\beta_h^2 + \frac{1}{\gamma_1}(2\beta_h' - y)y - \beta_h'}{\gamma_1}}. (46)$$

$$\beta_h = \beta_h + \frac{Y_{h1}}{2Y_{h2}}, \quad \beta_c = \beta_c + \frac{Y_{c1}}{2Y_{c2}} \gamma_1^2 = \frac{Y_{h2}}{Y_{c2}}. (47)$$

The power of this heat engine is given by

$$P = \frac{1}{2} N_0 h^2 \frac{X_h \nu_h^2 x - X_c \nu_c^2 y}{\tau_h + \tau_c}. (48)$$

It is maximized when $\partial P/\partial y = 0$. Let $\gamma_2' = \frac{X_c \nu_c^2}{X_h \nu_h^2}$, then we have $\frac{\partial y}{\partial y} = \frac{1}{\gamma_2'}. Using Eq. (46), the only meaningful solution for $y$ is

$$y = \frac{\beta_c'(\gamma_2 + \gamma_2^2) - \sqrt{\beta_c'^2 \gamma_2^2 + \beta_c'^2 \gamma_2^4}}{\gamma_2^2 + \gamma_2^2}. (49)$$

The efficiency of the thermal engine at maxinum power is

$$\eta_m = 1 - \frac{X_c \nu_c^2 y}{X_h \nu_h^2 x} = 1 - \frac{y}{\gamma_2} x. (50)$$

Plugging Eqs. (46) and (49) we have

$$\eta_m = 1 - \frac{\beta_c'}{\gamma_2} \gamma_2^2 (1 - \eta_c') - 1 + \frac{1}{\gamma_2} \sqrt{(1 + \gamma_1^2 (1 - \eta_c')^2)(\gamma_1^2 + \gamma_2^2)}. (51)$$

where $\eta_c' = 1 - \frac{\beta_h'}{\gamma_1}$ can be thought of as the corrected Carnot efficiency. If we chose suitable $E_{h,c}$ and $E_{h0,c0}$ such that $\gamma_1 = \gamma_2 = \gamma'$, Eq. (51) “recovers” the result of except that $\eta_c$ is replaced by $\eta_c'$ and $\gamma$ by $\gamma'$. By inspecting the numerators and denominators of $\gamma_1$ and $\gamma_2$, one can find that they are of the same order of $E_{h,c}$ and $E_{h0,c0}$ respectively. Hence it is reasonable to assume that they are of the same order when approaching 0 or $\infty$. Therefore we get a rough estimation of the upper and lower bounds

$$\frac{\eta_c'}{2} \leq \eta_m \leq \frac{\eta_c'}{2 - \eta_c'}. (52)$$

Following the same reasoning as before, the tighter bounds of $\eta_m$ are given by

$$\frac{2 - \sqrt{4 - 4\eta_c' + 2\eta_c'^2}}{2 - \eta_c'} \leq \eta_m \leq \frac{\eta_c'}{2 - \eta_c'}. (53)$$

Despite the similarity between the results associated with the B.E. distribution and those associated with the M.B. and F.D. distributions, there is also qualitative difference between them. Obviously the latter only depend on the difference of energy levels, or $\nu_{h,c}$. However, the former has an explicit dependence on the choice of initial (low) energy level $E_{h0,c0}$.

**Efficiency and its bounds in the short contact time limit**

We consider the limit that $\tau \ll 1/a$ and expand the inverse temperature to the second order of $a \tau$, then the
As before we match both sides of 
\[ \Delta \]
find

Using the same argument as in the last section, one can

\[ \eta \]
Interestingly, this also "recovers" the result (32) expect

\[ 0 \]

then the output power is evaluated as:

\[ \frac{\beta' \gamma_c + 2x}{x(\beta'_h + x)^2} = \gamma_1^2 \frac{\beta'_c - 2y}{y(\beta'_c - y)^2}. \]

Using the same argument as in the last section, one can find

\[ \frac{y}{x} = \gamma_1^2 \frac{\beta'_c - 2y}{y(\beta'_c - y)^2}. \]

The spontaneous emission coefficient \( A \) satisfies \( A \propto \nu^2 \), then the output power is evaluated as:

\[ P = \frac{1}{2} N_0 h^2 \nu^2 \mathcal{E}_{h \nu} x x a_h \mathcal{E}_h - \frac{\gamma_1^2 x x \beta'_h}{\beta'_c} - \frac{\gamma_1^2 x x \beta'_h}{\beta'_c} - \frac{2^2 x x \beta'_h}{\beta'_c} - \frac{2}{2^2 x x \beta'_h}, \]  

(59)

where \( \gamma_3 = \frac{\mathcal{E}_h (\mathcal{E}_h + \mathcal{E}_c)}{2 \mathcal{E}_h (\mathcal{E}_h + \mathcal{E}_c)} \). The power is maximized when \( \partial P / \partial x = 0 \), which leads to the solution of the efficiency at maximum power is

\[ \eta_m = \frac{\beta'_h \gamma_1^2 + \beta'_c \gamma_3 - \gamma_1^2 \sqrt{\beta'_h \beta'_c (1 + \gamma_3) (1 + \gamma_2) (1 + \gamma_1)}}{\beta'_h \beta'_c (1 + \gamma_3) (1 + \gamma_2) (1 + \gamma_1)} \]  

(60)

If \( E_{h, c} \) and \( E_{k, e, 0} \) are chosen suitably such that \( \gamma_1 = \gamma_2 = \gamma_3 = \gamma' \), the efficiency \( \eta_m \) can also be expanded in series of \( \eta'_c \) as

\[ \eta_m = \frac{\eta'_c}{2} + \frac{2^2}{8 \gamma_1 + 2^2 + \gamma_2 + \gamma_3} \eta_c^2 + O(\eta_c^3). \]  

(61)

Interestingly, this also "recovers" the result (32) expect that \( \eta_c \) is replaced by \( \eta'_c \) and \( \gamma \) by \( \gamma' \). Similarly, when \( \gamma' \) approaches 0, \( \eta_c \) or 1, \( \infty \), the rough and fine bounds of \( \eta_m \) are found to be

\[ \frac{\eta'_c}{2} \leq \eta_m \leq \frac{\eta'_c}{2 - \eta'_c}, \]  

\[ 1 - \sqrt{1 - \eta'_c} \leq \eta_m \leq \frac{\eta'_c}{2 - \eta'_c}. \]  

(62)

CONCLUSIONS

In conclusion, we presented an analysis of the quantum thermal engine of which the heat transferring law is derived from Einstein’s theory of radiation. Again we notice that heat transferring laws play a crucial role on the problems about the efficiency of quantum thermal engines at maximum power. The thermal efficiency and its bounds at maximum power for quantum Einstein engines are studied in the long and short time limits. To some extent, this can be thought as the quantum counterpart of the classical thermal engine studied in Ref. [3], which can simulate some well-known classical thermal engines. For \( \hbar \nu \ll 1 \), we find that the quantum Einstein engine with fermionic working substance has no difference from that with maxwellian working substance, while the one with bosonic working substance has a qualitative difference.
