Cochlear implant and tinnitus: a review

Santosh Kumar Swain*

ABSTRACT

Tinnitus is the perception of a sound without any external auditory input and patient experiences as a ringing or buzzing sound in the ear or head. Tinnitus is a common and troublesome clinical entity that has existed for centuries. However, the exact etiology for tinnitus is not known. Electrical suppression of the tinnitus by cochlear implant is a secondary benefit to many cochlear implant recipients. Cochlear implants are often helpful to improve speech perception for those suffered with severe to profound hearing loss where hearing aids are no longer beneficial. There is high prevalence of tinnitus among patients with profound hearing loss which often reduced after cochlear implant.

INTRODUCTION

Tinnitus is spontaneous, disagreeable auditory sensation, of varied origin with multiple etiologies. Tinnitus aurium means ringing of the ears and it can be classified into objective and subjective tinnitus. Objective tinnitus is defined as a sound which originates from the acoustic source within the patient and audible to the examiner whereas the subjective tinnitus has no acoustic tinnitus and the subjective tinnitus accounts for 95% of all types of tinnitus. Tinnitus is a common symptom found among patients with bilateral profound sensorineural hearing loss. Currently cochlear implant is a standard treatment for profound sensorineural hearing loss, and reportedly can minimize the tinnitus. This indication of cochlear implant has impact on tinnitus magnitude and annoyance also in patients with unilateral deafness. It is also unclear whether the psychological and physical changes which accompany aging process influence the relief of the tinnitus after cochlear implant. Unilateral cochlear implantation is commonly performed in patients with bilateral profound sensorineural hearing loss. The additional benefit of this treatment is the reduction of subjective tinnitus. Interestingly, the sole cochlear implantation surgery itself may have positive impact on tinnitus. It seems reasonable to suggest that positive expectations of patients with cochlear implants may have role in improvement of tinnitus. Study is also presenting with increasing tinnitus occurrence in 0% to 25% patients. The development of newly induced tinnitus following cochlear implantation ranges from 0% to 10% among patients without preoperative tinnitus. Because of
increase of tinnitus and newly induced tinnitus following cochlear implant, a positive impact of cochlear implantation on the individual patient presenting or experiencing tinnitus cannot be predicted for certain. There are not much research concerning cochlear implantations and the effect on tinnitus. This review article will discuss on epidemiology, pathophysiology, cochlear implant surgery and tinnitus, severity of tinnitus, evaluation of tinnitus and current treatment of newly induced tinnitus after cochlear implantation.

METHODS OF LITERATURE SEARCH

Multiple systematic methods were used to find current research publications on cochlear implant and tinnitus. We started by searching the Scopus, PubMed, Medline, and Google Scholar databases online. A search strategy using PRISMA (Preferred reporting items for systematic reviews and meta-analysis) guidelines was developed. This search strategy recognized the abstracts of published articles, while other research articles were discovered manually from the citations. Randomized controlled studies, observational studies, comparative studies, case series, and case reports were evaluated for eligibility. There were total numbers of articles 94 (32 case reports; 34 cases series; 28 original articles) (Figure 1). This paper focuses only on tinnitus following cochlear implantation. This paper examines the epidemiology, pathophysiology, tinnitus following cochlear implant surgery, evaluation of severity of tinnitus and treatment of pre-cochlear implant tinnitus. This analysis provides a foundation for future prospective trials in cochlear implant and tinnitus. It will also serve as a catalyst for additional study into cochlear implant and its relation to tinnitus.

HISTORY

Jastreboff’s neurophysiological model suggested the importance of the interaction of central auditory system, limbic system and the sympathetic autonomic system. The therapeutic effect of cochlear implant in preoperatively existing tinnitus had already been documented in the history of cochlear implant. In House and Brackmann documented that patient with cochlear implants get improvement of the previously existing tinnitus. This history suggests that possibility of using cochlear implantation help patients suffering from severe tinnitus. At one time or another, approximately 35% of the general population has suffered from tinnitus. In approximately 5% of the population, tinnitus is responsible for difficulties in falling asleep or shows a moderate to intense problem. Approximately 0.5% to 1% of the population experiences tinnitus which severely affects the routine life. As per this model, peripheral lesions generate an electrical signal, added to an efficient control of the encephalic stem system and to behavioral and emotional reactions, results in an unpleasant ringing or buzzing sensation.

EPIDEMIOLOGY

Tinnitus is a highly disturbing clinical entity, with high prevalence in sensorineural hearing loss patients. Subjective tinnitus has prevalence of 8% to 15% in general adult population. One study estimated the prevalence of adults with chronic tinnitus varies between 6% to 20%. The prevalence of tinnitus among bilateral profound sensorineural hearing loss is 65% to 100% with mean of approximately 80%. Several studies seem to confirm the clinical findings that cochlear implant has a marked suppressive effect on tinnitus in majority of cochlear implant users. However, there are some uncertainties regarding to the prevalence and severity of tinnitus in profound sensorineural hearing loss patients, as well as suppression of tinnitus after cochlear implant. The prevalence of tinnitus in cochlear implant candidates ranges from 67% to 86%. One study showed that total tinnitus suppression rates vary from 2% to 83%. However, an increase of existing tinnitus ranges from 2% to 9%, as well as a new onset of tinnitus. The induction of tinnitus found in 1% to 5% of patients as per recent study. Around 1% to 3% suffered disabling tinnitus interferes with their quality of life.

PATHOPHYSIOLOGY

The exact pathophysiology of the tinnitus is not known. Most of the hypothesis state that tinnitus occurs due to maladaptive plastic changes in the central auditory pathways as a reaction to the peripheral hearing loss. Recent studies demonstrated that occurrence of the neuronal plasticity and cortical reorganization in relation to perception of sound after injury to the cochlea. The disproportional increase in number of neurons sensitive to remaining frequencies of hearing or greater spontaneous activity in organized locations may explain the tinnitus sensation. The high prevalence of tinnitus is consistent with the fact that individuals with hearing loss are more likely to suffer from tinnitus. Reduction of the tinnitus after cochlear implants is better explained by several mechanisms like acoustic masking, habituation, direct stimulation of the auditory nerve and reorganization of the cortical areas. Tinnitus is considered
TINNITUS AND COCHLEAR IMPLANT SURGERY

Study suggested that electrical promontory stimulation is effective in suppression of the tinnitus. Reduced tinnitus has been documented after cochlear implant surgery. The insertion of electrode of cochlear implant was a trauma to the remaining functional components of cochlea and thought to affect both necrotic and apoptic mechanisms of cell death and such insertion of electrode may influence the tinnitus among cochlear implant patients. However, there may be improvement of tinnitus with electrode insertion which described by some research papers, though the positive expectations of the patients in relation to implant may be a factor. There are few reports in patients with cochlear implant where electrode insertion exacerbates the tinnitus (>10%) or aggravates it being heard for the first time (>4%). There are also changes in tinnitus pitch and timber in cochlear patients. The post-surgical cochlear implant provides benefits in terms of tinnitus which raises few questions such as cochlear implant surgery justifiable for treatment of tinnitus. Similarly, the influence of tinnitus according to choose of ear for cochlear implant is also a complex subject. Some suggests that cochlear implant in the ear where tinnitus is more severe has chance for greater suppression.

EVALUATION OF SEVERITY OF TINNITUS

Tinnitus handicap questionnaire (THQ) is used to measure the perception of physical and psychological well-being in tinnitus patients. It consists of 27 questions classified into three categories such as social, emotional and behavioral tinnitus effects; tinnitus and hearing; and outlook on tinnitus. Patients respond whether or not they agreed with statements on a scale of 0 to 100. Total scores are calculated per category, after which the mean value of THQ is calculated. Tinnitus handicap inventory (THI) questionnaires consist of 25 questions for influence of tinnitus on activities of daily life. There are 11 questions for functional effects on tinnitus, 9 questions for emotional responses to tinnitus, and 5 questions for catastrophic responses to tinnitus. Here, every ‘yes’ counts for 4 points, every ‘sometimes’ for 2 points and every ‘never’ for 0 points. There is total score between 0 and 100. Scores less than 16 indicate slight handicap, scores from 18 to 38 indicate mild tinnitus, scores from 38 to 56 correspond to severe tinnitus, and scores more than 78 indicate catastrophic tinnitus. One study showed tinnitus improvement after six months with CI fitting and 36% reported total loudness suppression and another 41% reported a reduction; annoyance scores reduced in 75% of patients and 72.2% reported these benefits in the THI questionnaire. Tinnitus significantly affect the quality of life and may cause stress, depression, anxiety and may result in suicidal tendencies in some patients. Reports have been documented the possibility of tinnitus worsening or being exacerbated following cochlear implant surgery. Few patients developed postsurgical onset of tinnitus and labyrinthine symptoms when the implant is activated. The probable explanation for this tinnitus us that program adjustment is not happened owing to the short period of activation.

TREATMENT OF PRE-COCHLEAR IMPLANT TINNITUS

Many patients those with sensorineural hearing loss present with tinnitus, particularly those with an indication for cochlear implant. Although several treatment options have been recommended for managing tinnitus, none of them has been total effective for abolishing the tinnitus. If the tinnitus disturbs the sleep i.e., troublesome tinnitus may need programming of cochlear implant device for night time use. There are two options: first one utilizes a program which facilitates night time use of an environmental sound like wind, rain or ocean sound and this is effective as tinnitus therapy in persons with hearing. The second option considers an implant electrode configuration which provides barely supra-threshold stimulation in night to decrease the awareness of the tinnitus. As in hearing aids, optimization of the cochlear implant for tinnitus may involve programming which decreases speech discrimination abilities. The tinnitus program should be addition to the program which is in general use of the cochlear implant (speech communication). There is an ongoing worldwide discussion on whether or not bilateral cochlear implantation should be standard care towards bilateral severe to profound deafness. Contrary to unilateral cochlear implantation, however, study reported on the impact of bilateral cochlear implantation on tinnitus where the bilateral cochlear implantation has positive effect on preoperative tinnitus. In sequential group of patients for cochlear implantation, the additional benefit of the second cochlear implant is total suppression of tinnitus in comparison to unilateral situation.

POST-COCHLEAR IMPLANT TINNITUS

Tinnitus is a common occurrence in pediatric age group those undergo cochlear implantation. The higher...
prevalence of tinnitus is in patients with cochlear implantation than non-implanted children with profound hearing loss.43 There was no evidence that prevalence of tinnitus was influenced by hearing loss, time elapsed since implantation and age at cochlear implantation. In children with bilateral cochlear implants, there is increased evidence of tinnitus in those with a longer inter-implant delay than those with a short delay or simultaneous implantation.43 Although the high tinnitus prevalence, quality of life is less affected with a small proportion of pediatric patients reporting sleep disturbances. Prevalence of tinnitus among children with normal and impaired hearing are given in Table 1.44-48

Table 1: Prevalence of tinnitus among children with normal and impaired hearing.

CONCLUSION

Tinnitus is a common clinical problem associated with cochlear implant candidates and cochlear implant users. Cochlear implant is often helpful to reduce tinnitus and tinnitus handicap. A short duration of tinnitus before cochlear implantation, a tonal tinnitus, a higher tinnitus handicap prior to implantation, and a round window insertion surgical technique correlate with an optimistic influence of cochlear implantation on the tinnitus. Although cochlear implant improves or stabilize the tinnitus perception in most of adult cochlear implant receivers, only rarely does total elimination of the tinnitus. The variable effect of cochlear implant on tinnitus remains unexplained. This may be due to absence of residual inhabitation of tinnitus in patient using multichannel cochlear implants. Further research is required in larger and a more uniform study population in regards to hearing abilities, type of tinnitus (unilateral/tonal) and age of the patients.
