Abstract

We study analytically the initial value problem for a self-interacting (massive) scalar-field on a Reissner-Nordström spacetime. Following the no-hair theorem we examine the dynamical physical mechanism by which the self-interacting (SI) hair decays. We show that the intermediate asymptotic behaviour of SI perturbations is dominated by an oscillatory inverse power-law decaying tail. We show that at late-times the decay of a SI hair is slower than any power-law. We confirm our analytical results by numerical simulations.

I. INTRODUCTION

The late-time evolution of various fields outside a collapsing star has an important implications to two major aspects of black-hole physics: the no-hair theorem and the mass-Inflation scenario. The no-hair theorem, introduced by Wheeler in the early 1970s, states that the external field of a black-hole relaxes to a Kerr-Newman field characterized solely by the black-hole’s mass, charge and angular-momentum. Thus, it is of interest to explore the dynamical physical mechanism responsible for the relaxation of perturbations fields outside a black-hole and to determine the decay-rates of the various perturbations (which differ from one field to the other). The mechanism by which massless neutral fields are radiated away was first studied by Price [1]. The physical mechanism by which a massless charged scalar
hair is radiated away was studied in \cite{2,3}. In this paper we study the physical mechanism responsible for the decay of a *self-interacting (massive)* scalar-hair.

The asymptotic late-time tails along the outer horizon of a rotating or a charged black-hole are used as initial input for the ingoing perturbations which penetrates into the black-hole. These perturbations are the physical cause for the well-known phenomena of *mass-inflation* \cite{4}. In this context, one should take into account the existence of *massive* tails outside the collapsing star. Here we study analytically the intermediate asymptotic behaviour of such self-interacting (massive) perturbations fields. We study the late-time asymptotic behaviour numerically and confirm the numerical results of Burko \cite{5}.

The plan of the paper is as follows. In Sec. II we describe the physical system and formulate the evolution equation considered. In Sec. III we formulate the problem in terms of the black-hole Green’s function using the technique of spectral decomposition (this section is analogous to the one given in \cite{3}). In Sec. IV we study the intermediate asymptotic evolution of SI scalar perturbations on a Reissner-Nordstr"{o}m background. We find an oscillatory inverse power-law behaviour of the perturbations at a fixed radius and along the black-hole outer-horizon. We find that the dumping exponents which describe the intermediate fall-off of SI perturbations are smaller compared with the massless (neutral) dumping exponents. In Sec. V we verify our analytical results by numerical simulations. We conclude in Sec. VI with a brief summary of our results and their implications.

**II. DESCRIPTION OF THE SYSTEM**

We consider the evolution of SI scalar perturbation fields outside a collapsing star. The external gravitational field of a spherically symmetric collapsing star of mass $M$ and charge $Q$ is given by the Reissner-Nordstr"{o}m metric

$$ds^2 = - \left( 1 - \frac{2M}{r} + \frac{Q^2}{r^2} \right) dt^2 + \left( 1 - \frac{2M}{r} + \frac{Q^2}{r^2} \right)^{-1} dr^2 + r^2 d\Omega^2 .$$

Using the tortoise radial coordinate $y$, defined by $dy = dr/\lambda^2$ where $\lambda^2 = 1 - \frac{2M}{r} + \frac{Q^2}{r^2}$, the metric becomes
\[ ds^2 = \lambda^2 (-dt^2 + dy^2) + r^2 d\Omega^2 , \]

(2)

The wave equation for the SI scalar-field is

\[ \phi_{,ab} g^{ab} - U'(|\phi|^2) \phi = 0 , \]

(3)

where \( U(|\phi|^2) \) is the self-interaction potential and \( U''(|\phi|^2) = dU(|\phi|^2)/d\phi^* \). Since we study the evolution of small perturbations we approximate \( U''(|\phi|^2) \) by \( m^2 \phi \) (we assume that \( m \) is real), neglecting terms of higher order in \( \phi \). Resolving the field into spherical harmonics \( \phi = \sum_{l,m} \psi_m \left( t, \frac{r}{\phi} \right) Y_l^m (\theta, \varphi) / r \) one obtains a wave-equation for each multiple moment

\[ \psi_{,tt} - \psi_{,yy} + V \psi = 0 , \]

(4)

where

\[ V = V_{M,Q,l,m} (r) = \left( 1 - \frac{2M}{r} + \frac{Q^2}{r^2} \right) \left[ \frac{l(l+1)}{r^2} + \frac{2M}{r^3} - \frac{2Q^2}{r^4} + m^2 \right] . \]

(5)

### III. FORMALISM

The time-evolution of a SI scalar-field described by Eq. (4) is given by

\[ \psi(y, t) = \int \left[ G(y, x; t) \psi_t(x, 0) + G_t(y, x; t) \psi(x, 0) \right] dx , \]

(6)

for \( t > 0 \), where the (retarded) Green’s function \( G(y, x; t) \) is defined as

\[ \left[ \frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial y^2} + V(r) \right] G(y, x; t) = \delta(t) \delta(y - x) . \]

(7)

The causality condition gives us the initial condition \( G(y, x; t) = 0 \) for \( t \leq 0 \). In order to find \( G(y, x; t) \) we use the Fourier transform

\[ \tilde{G}(y, x; w) = \int_0^{\infty} G(y, x; t) e^{iwt} dt . \]

(8)

The Fourier transform is analytic in the upper half \( w \)-plane and it satisfies

\[ \left( \frac{d^2}{dy^2} + w^2 - V \right) \tilde{G}(y, x; w) = \delta(y - x) . \]

(9)
\( G(y, x; t) \) itself is given by the inversion formula

\[
G(y, x; t) = \frac{1}{2\pi} \int_{-\infty+ic}^{\infty+ic} \tilde{G}(y, x; w)e^{-iwt}dw ,
\]

(10)

where \( c \) is some positive constant.

Next, we define two auxiliary functions \( \tilde{\psi}_1(y, w) \) and \( \tilde{\psi}_2(y, w) \) which are linearly independent solutions to the homogeneous equation

\[
\left( \frac{d^2}{dy^2} + w^2 - V \right) \tilde{\psi}_i(y, w) = 0 , \quad i = 1, 2 .
\]

(11)

Let the Wronskian be

\[
W(w) = W(\tilde{\psi}_1, \tilde{\psi}_2) = \tilde{\psi}_1 \tilde{\psi}_2,y - \tilde{\psi}_2 \tilde{\psi}_1,y ,
\]

(12)

where \( W(w) \) is \( y \)-independent. Using the two solutions \( \tilde{\psi}_1 \) and \( \tilde{\psi}_2 \), the black-hole Green’s function can be expressed as

\[
\tilde{G}(y, x; w) = -\frac{1}{W(w)} \begin{cases} 
\tilde{\psi}_1(y, w)\tilde{\psi}_2(x, w) & , \quad y < x , \\
\tilde{\psi}_1(x, w)\tilde{\psi}_2(y, w) & , \quad y > x .
\end{cases}
\]

(13)

In order to calculate \( G(y, x; t) \) using Eq. (10), one may close the contour of integration into the lower half of the complex frequency plane. Then, one finds three distinct contributions to \( G(y, x; t) \):

1. **Prompt contribution.** This arises from the integral along the large semi-circle. It is this part, denoted \( G^F \), which propagates the high-frequency response. For large frequencies the Green’s function approaches to the one of a massless scalar-field on a flat spacetime background. This term contributes to the short-time response and can be shown to be effectively zero beyond a certain time. Thus, it is not relevant for the late-time behaviour of the field.

2. **Quasinormal modes.** These arise from the distinct singularities of \( \tilde{G}(y, x; w) \) in the lower half of the complex \( w \)-plane and is denoted by \( G^Q \). These singularities occur at frequencies for which the Wronskian (12) vanishes. \( G^Q \) is just the sum of the residues
at the poles of $\tilde{G}(y, x; w)$. Since each mode has $\text{Im} w < 0$ it decays *exponentially* with time.

3. **Tail contribution.** As will be shown later the intermediate asymptotic tail is associated with the existence of a branch cut (in $\tilde{\psi}_2$) placed along the interval $-m \leq w \leq m$. This tail arises from the integral of $\tilde{G}(y, x; w)$ around the branch cut (denoted by $G^C$) which leads to an *oscillatory* inverse *power-law* behaviour of the field. Since we are interested in the intermediate asymptotic behaviour of a SI scalar-field our goal is to evaluate $G^C(y, x; t)$.

### IV. THE INTERMEDIATE ASYMPTOTIC BEHAVIOUR OF A SELF-INTERACTING SCALAR-FIELD

**A. The $M \ll r \ll M/(Mm)^2$ approximation**

It is well known that the late-time behaviour of *massless* fields is determined by the backscattering from asymptotically *far* regions [7,1,2]. Thus, the late-time tails of massless fields are dominated by the *low*-frequencies contribution to the Green’s function, for only low frequencies will be backscattered by the small spacetime curvature or by the small electromagnetic interaction at these asymptotic regions. On the other hand, it is also well known that *massive*-tails exist even in a *flat* spacetime [8]. This phenomena is related to the fact that different frequencies forming a massive wave packet have different phase velocities. As will be shown in this paper, the intermediate asymptotic behaviour of a *SI* scalar-field on a Reissner-Nordström background is dominated by *flat* spacetime effects. Namely, at intermediate times the backscattering from asymptotically *far* regions (which dominates the tails of massless fields) is *negligible* compared to the flat spacetime massive tails that appear here.

Let us assume that both the observer and the initial data are situated far away from the black-hole. We expend the wave-equation (11) for the SI scalar-field (in the field of
the black-hole) as a power series in $M/r$ and $Q/r$ and obtain (neglecting terms of order $O[(Mm)^2]$ and higher)

$$\left[ \frac{d^2}{dr^2} + w^2 - m^2 + \frac{4Mw^2 - 2Mm^2}{r} - \frac{l(l+1)}{r^2} \right] \xi = 0 ,$$

(14)

where $\xi = \lambda \tilde{\psi}$. The term proportional to $M/r$ represent the Newtonian potential. If we further assume that both the observer and the initial data are situated in the region $r \ll M/(Mm)^2$ (and $M \ll r$), and we are interested in the intermediate asymptotic behaviour of the field ($r \ll t \ll M/(Mm)^2$) we can further approximate Eq. (14) by

$$\left[ \frac{d^2}{dr^2} + w^2 - m^2 \right] \xi = 0 ,$$

(15)

Replacing Eq. (14) with Eq. (15) means that we neglect the backscattering of the field from asymptotically far regions. Thus, the intermediate asymptotic behaviour of SI scalar perturbations on a black-hole (or a star) background depends only on the field’s parameters (namely, on the mass of the field) and it does not depend on the spacetime parameters. The validity of this conclusion is verified by numerical simulations (see Sec. V).

Let us now introduce a second auxiliary field $\tilde{\phi}$ defined by

$$\xi = r^{l+1} e^{i\sqrt{w^2 - m^2} r} \tilde{\phi}(z) ,$$

(16)

where

$$z = -2iwr .$$

(17)

$\tilde{\phi}(z)$ satisfies the confluent hypergeometric equation

$$\left[ z \frac{d^2}{dz^2} + (2l + 2 - z) \frac{d}{dz} - (l + 1) \right] \tilde{\phi}(z) = 0 .$$

(18)

The two basic solutions required in order to build the black-hole Green’s function are (for $|w| \leq m$)

$$\tilde{\psi}_1 = Ar^{l+1} e^{-\varpi r} M(l + 1, 2l + 2, 2\varpi r) ,$$

(19)

and
\psi_2 = Br^{l+1}e^{-\varpi r}U(l+1,2l+2,2\varpi r) ,  \quad (20)

where \varpi = \sqrt{m^2 - w^2}$. $A$ and $B$ are normalization constants. $M(a,b,z)$ and $U(a,b,z)$ are the two standard solutions to the confluent hypergeometric equation [3]. $U(a,b,z)$ is a many-valued function, i.e. there is a cut in $\tilde{\psi}_2$. Using Eqs. 13.6.6 and 13.6.24 of [3] one may write these solutions in a more familiar form

\begin{align*}
\tilde{\psi}_1 &= \frac{1}{2}Ar^{\frac{3}{2}}(l + \frac{3}{2})(\frac{1}{2}\varpi)^{-(l+\frac{3}{2})}I_{l+\frac{3}{2}}(\varpi r) , \quad (21)
\end{align*}

and

\begin{align*}
\tilde{\psi}_2 &= \pi^{-\frac{1}{2}}Br^{\frac{1}{2}}(2\varpi)^{-(l+\frac{1}{2})}K_{l+\frac{1}{2}}(\varpi r) , \quad (22)
\end{align*}

where $I_{l+\frac{1}{2}}$ and $K_{l+\frac{1}{2}}$ are the modified Bessel functions.

Using Eq. (10), one finds that the branch cut contribution to the Green’s function is given by

\begin{align*}
G^C(y,x;t) = \frac{1}{2\pi} \int_{-m}^{m} \tilde{\psi}_1(x,\varpi) \left[ \frac{\tilde{\psi}_2(y,\varpi e^{\pi i})}{W(\varpi e^{\pi i})} - \frac{\tilde{\psi}_2(y,\varpi)}{W(\varpi)} \right] e^{-iwt} dw . \quad (23)
\end{align*}

For simplicity we assume that the initial data has a considerable support only for $r$-values which are smaller than the observer’s location. This, of course, does not change the late-time behaviour.

Using Eqs. 9.6.30 and 9.6.31 of [3], one finds

\begin{align*}
\tilde{\psi}_1(r,\varpi e^{\pi i}) = \tilde{\psi}_1(r,\varpi) , \quad (24)
\end{align*}

and

\begin{align*}
\tilde{\psi}_2(r,\varpi e^{\pi i}) = -\tilde{\psi}_2(r,\varpi) + \frac{B}{A} \frac{\pi^{\frac{1}{2}}(-1)^{l+1}2^{-2l}}{\Gamma(l+\frac{3}{2})} \tilde{\psi}_1(r,\varpi) . \quad (25)
\end{align*}

Using Eqs. (24) and (25) it is easy to see that

\begin{align*}
W(\varpi e^{\pi i}) = -W(\varpi) . \quad (26)
\end{align*}

From which we obtain the relation
\[
\frac{\tilde{\psi}_2(r, \varpi e^{\pi i})}{W(\varpi e^{\pi i})} - \frac{\tilde{\psi}_2(r, \varpi)}{W(\varpi)} = \frac{B \pi^{\frac{1}{2}} (-1)^{l+2l} \tilde{\psi}_1(r, \varpi)}{A \Gamma(l + \frac{3}{2}) W(\varpi)} .
\]  

(27)

Since \( W(\varpi) \) is \( r \)-independent, we may use the \( \varpi r \to 0 \) asymptotic expansions of the Bessel functions (given by Eqs. 9.6.7 and 9.6.9 in [9]) in order to evaluate it. One finds
\[
W(\varpi) = -\frac{1}{4} AB \pi^{-\frac{1}{2}} (2l + 1) \Gamma(l + \frac{1}{2}) \varpi^{-(2l+1)} .
\]  

(28)

Finally, substituting (27) and (28) in (23) we obtain
\[
G^C(y, x; t) = (-1)^{l+1} \pi^{\frac{1}{2}} m^{l+1} (xy)^{l-(l+1)} J_{l+1}(mt) ,
\]  

(29)

\[ \int_0^m \tilde{\psi}_1 (y, \varpi) \tilde{\psi}_1 (x, \varpi) \varpi^{2l+1} e^{-iwt} dw .
\]

B. Intermediate asymptotic at a fixed radius

It is easy to verify that in the large \( t \) limit the effective contribution to the integral in (29) arise from \( |w|=O(m - \frac{1}{t}) \) or equivalently \( \varpi = O(\sqrt{\frac{m}{t}}) \). This is due to the rapidly oscillating term \( e^{-iwt} \) which leads to a mutual cancelation between the positive and the negative parts of the integrand. In order to obtain the intermediate asymptotic behaviour of the field at a fixed radius (where \( x, y \ll t \)), we may use the \( \varpi r \ll 1 \) limit of \( \tilde{\psi}_1(r, \varpi) \). Using Eq. 9.6.7 from [9] one finds
\[
\tilde{\psi}_1(r, \varpi) \approx \frac{1}{2} Ar^{l+1} .
\]  

(30)

We obtain
\[
G^C(y, x; t) = \frac{(-1)^{l+1} \pi^{\frac{1}{2}} m^{l+1}}{2^l (2l + 1) \Gamma(l + \frac{1}{2})} (xy)^{l-(l+1)} J_{l+1}(mt) ,
\]  

(31)

which in the \( t \gg m^{-1} \) limit becomes
\[
G^C(y, x; t) = \sqrt{\frac{2}{\pi}} \frac{(-1)^{l+1}}{(2l + 1)!!} m^{l+\frac{1}{2}} (xy)^{l+1} t^{-(l+\frac{3}{2})} \cos[mt - (\frac{1}{2} l + \frac{3}{4})\pi] .
\]  

(32)

Thus, the intermediate asymptotic behaviour of the SI field at a fixed radius is dominated by an oscillatory inverse power-law tail.
C. Intermediate asymptotic along the black-hole outer horizon

Next, we consider the behaviour of the SI scalar-field at the black-hole outer-horizon \( r_+ \). While Eqs. (21) and (22) are approximate solutions to the wave-equation (11) in the \( M \ll r \ll M/(Mm)^2 \) region, they do not represent the solution near the horizon. As \( y \to -\infty \) the wave-equation (11) can be approximated by the equation

\[
\ddot{\psi}_{yy} + w^2 \psi = 0 .
\] (33)

Thus, we chose

\[
\tilde{\psi}_1(y, w) = C(w) e^{-iwy} ,
\] (34)

and we use the form (31) for \( \tilde{\psi}_1(x, w) \). In order to match the \( y \ll -M \) solution to the \( y \gg M \) solution we assume that the two solutions have the same temporal dependence. This assumption has been proven to be very successful for massless neutral [10] and charged [2,3] perturbations. In other words we assume that \( C(w) \) is \( w \)-independent. In this case one should replace the roles of \( x \) and \( y \) in Eqs. (23) and (29). Using (29), we obtain

\[
G^C(y, x; t) = \Gamma_0 \sqrt{\frac{2}{\pi(2l + 1)!!}} m^{l+\frac{1}{2}} y^{l+1} v^{-(l+\frac{3}{2})} \cos[mv - \left( \frac{1}{2}l + \frac{3}{4} \right)\pi] ,
\] (35)

where \( \Gamma_0 \) is a constant.

Thus, the intermediate asymptotic behaviour of the SI field along the black-hole outer-horizon is dominated by an oscillatory inverse power-law tail.

V. NUMERICAL RESULTS

It is straightforward to integrate Eq. (4) using the method described in [10]. The late-time evolution of a SI scalar-field is independent of the form of the initial data used. The results presented here are for a Gaussian pulse on \( u = 0 \)

\[
\psi(u = 0, v) = A \exp \left\{ - \left[ (v - v_0)/\sigma \right]^2 \right\} ,
\] (36)
where the amplitude $A$ is physically irrelevant due to the linearity of Eq. (I). It should be noted that the evolution equation (I) is invariant under the rescaling

$$r \rightarrow ar, \ t \rightarrow at, \ M \rightarrow aM, \ Q \rightarrow aQ, \ m \rightarrow m/a,$$

(37)

where $a$ is some positive constant. The black-hole mass and charge are set equal to $M = 0.5$ and $Q = 0.45$, respectively. We have chosen an initial field-profile with $m = 0.01$, $v_0 = 50$ and $\sigma = 2$. We studied the behaviour of the field $\psi$ at a fixed radius and along the black-hole outer horizon (approximated by the null surface $u = u_{max}$, where $u_{max}$ is the largest value of $u$ on the grid). The numerical results for the $l = 0$ mode are shown in Fig. 1. Initially, the evolution is dominated by the prompt contribution and the quasinormal ringing. However, at intermediate times a definite oscillatory power-law fall off is manifest. The power-law exponents are $-1.48$ at a fixed radius (top curve) and $-1.47$ along the black-hole outer-horizon (bottom curve). These values are to be compared with the analytically predicted value of $-1.5$, see Eqs. (32) and (35). The period of the oscillations (for $|\psi|$) equals $T = \pi/m$ to within 0.1%, again in agreement with the predicted value. Fig. 2. depicts the dependence of the intermediate asymptotic tails (at a fixed radius $y = 50$) on the multipole index $l$. The numerical values of the power-law exponents, describing the fall-off of the field at intermediate times (after a period of quasinormal ringing) are $-1.49, -2.50, -3.50$ and $-4.51$ for $l=0,1,2$ and 3, respectively. These numerical values are in excellent agreement with the analytically predicted values of $-1.5, -2.5, -3.5$ and $-4.5$. Again, the period of the oscillations is $T = \pi/m$ to within 0.1%, in agreement with the predicted value.

The analytical derivations and their numerical confirmations presented so far are restricted to the intermediate asymptotic regime. The late-time evolution of the field (for the $l = 0$ mode) is shown in Fig. 3 (for the clarity of the figure we display only the maximas of the oscillations). The initial data are those of Fig. 4. Shown are the behaviour of the field $|\psi|$ along the asymptotic regions of timelike infinity $i_+$ (top curve) and along the black-hole outer horizon (bottom curve). It is clear that the field’s amplitude decays with time, in agreement with the no-hair theorem. The decay rate is slower than any power-law. Again,
we find that the field $|\psi|$ oscillates with a period of $T = \pi/m$ to within 0.2%. We have found that the larger is the field’s mass the sooner it leaves the intermediate asymptotic phase of an inverse power-law decay.

VI. SUMMARY AND PHYSICAL IMPLICATIONS

We have studied analytically the intermediate asymptotic evolution of a SI scalar-field on a Reissner-Nordström background. Following the no-hair theorem we have focused attention on the physical mechanism by which a SI hair decays. The main results and their physical implications are:

Oscillatory inverse power-law tails develop at intermediate times at a fixed radius and along the black-hole outer horizon (as long as the initial data has a considerable support only in the region $M \ll r \ll \frac{M}{(Mm)^2}$. Actually, our analytical derivations hold even in the case $M \ll r \ll \frac{M(l+1)}{(Mm)^2}$ for $l > 0$). The dumping exponents, describing the fall-off of a SI field at intermediate times, are smaller compared with those of massless neutral perturbations [1,10]. For $l > \frac{2}{\sqrt{3}}|eQ| - \frac{1}{2}$ (where $e$ is the field’s charge) these dumping exponents are also smaller than those of massless charged perturbations [3]. While the asymptotic behaviour of massless perturbations is dominated by backscattering from asymptotically far regions [and thus depends on the spacetime parameters, $M$ (for neutral perturbations) and $Q$ (for charged perturbations)], the intermediate asymptotic behaviour of a SI field depends on the field’s parameters (namely, on the field’s mass $m$). In other words, dealing with SI perturbations, one may neglect the backscattering from asymptotically far regions at intermediate times.

Using the numerical scheme we have shown that at late-times the inverse power-law decay is replaced by another pattern of decay, which is slower than any power-law. This late-time behaviour deserves a further analytic study. The late-time behaviour of SI perturbations implies that a black-hole which forms from a gravitational collapse of SI fields becomes “bald” slower than one which forms during a gravitational collapse of massless fields. Since SI perturbation fields decay at late-times slower than any power-law they are
expected to cause a *mass-inflation* singularity during a gravitational collapse which leads to the formation of a black-hole. Moreover, SI fields are expected to *dominate* the mass-inflation phenomena during a gravitational collapse (this is caused by the *slower* decay of SI perturbations compared with massless ones).

We have confirmed our *analytical* results by numerical calculations, showing that the intermediate asymptotic behaviour of a SI field is dominated by an *oscillatory inverse power-law* tail (with the analytically predicted dumping exponents and oscillation frequency).

FIG. 1. Evolution of the SI field $|\psi|$ on a Reissner-Nordström background, for $l = 0, M = 0.5, Q = 0.45$ and $m = 0.01$. The initial data is a Gaussian distribution with $v_0 = 50$ and $\sigma = 2$. The field at a fixed radius ($y = 50$) is shown as a function of $t$. Along the black-hole outer horizon the field is shown as a function of $v$. The oscillatory power-law fall off is manifest at intermediate times. The power-law exponents are $-1.48$ at a fixed radius (top curve) and $-1.47$ along the black-hole outer-horizon (bottom curve). These values are to be compared with the analytically predicted value of $-1.5$. The period of the oscillations is $T = \pi/m$ to within 0.1%, in agreement with the predicted value.
FIG. 2. The amplitude of the field $|\psi(y = 50, t)|$ for different multipoles $l=0,1,2$ and 3 (from top to bottom). The power-law exponents are $-1.49, -2.50, -3.50$ and $-4.51$, respectively, in excellent agreement with the analytically predicted values of $-1.5, -2.5, -3.5$ and $-4.5$. The oscillations period is $T = \pi/m$ to within 0.1%, in agreement with the predicted value. The initial data are those of Fig. [1].
FIG. 3. Late-time evolution of the SI field $|\psi|$ on a Reissner-Nordström background. The field at future timelike infinity ($y = 50$) is shown as a function of $t$ (top curve). Along the black-hole outer horizon the field is shown as a function of $v$ (bottom curve). For the clarity of the figure we display only the maxima of the oscillations (the field oscillates with a period of $T = \pi/m$ to within 0.2%). At late-times the field’s amplitude decays slower than any power-law. The initial data are those of Fig. [1].
