Abstract. We have characterized the structure and function of RNA sequences that direct β-cytoplasmic actin mRNA to the cell periphery were mapped to two segments of 3'-untranslated region by expression of LacZ/β-actin chimeric mRNAs in chicken embryo fibroblasts (CEFs). A 54-nt segment, the "RNA zip-code," and a homologous but less active 43-nt segment each localized β-galactosidase activity to the leading lamellae. This zipcode contains the full activity, and mutations or deletions within it reduce, but do not eliminate, its activity, indicating that several motifs contribute to the activity. Two of these motifs, when multimerized, can regenerate almost full activity. These sequences are highly conserved in evolution, since the human β-actin zipcode, positioned identically in the 3'UTR localizes equally well in chicken cells. Complementary phosphorothioate oligonucleotides against the zipcode delocalized endogenous β-actin mRNA, whereas those complementary to the region just outside the zipcode, or sense oligonucleotides, did not. Actin mRNA or protein levels were unaffected by the antisense treatments, but a dramatic change in lamellipodia structure, and actin stress fiber organization was observed using the same antizipcode oligonucleotides which delocalized the mRNA. Hence, discrete 3'UTR sequences direct β-actin isoform synthesis to the leading lamellae and affect cell morphology, presumably through the actin cytoskeleton.

Actin is a highly abundant structural constituent of all eukaryotic cells integral to a variety of cellular functions. As a major constituent of the cytoskeleton or myofilaments, it is essential for the maintenance of cell polarity and motility (Bretcher, 1991; Cooper, 1991; Levitt et al., 1987; Pollard and Goldman, 1993), intracellular transport (Kuznetsov et al., 1992), protein synthesis (Hesketh and Pryme, 1991; Negrutskii and Deutscher, 1991; Yang et al., 1990), enzymatic processes (Farwell et al., 1990; Hunt et al., 1990; Knoll and Walsh, 1992; Sarndahl et al., 1989), and mRNA localization (Singer, 1992). Recent work indicated that the β-actin RNA localization signal ("zipcode") is contained within the 3'UTR and not in either the 5'UTR or the coding region (Kislauskis et al., 1993; Singer, 1993).

The precise characterization of essential RNA localization determinants is a prerequisite for understanding the mechanism by which mRNAs are localized, and elucidating the functional significance of this localization. Therefore, we undertook an extensive analysis of the cis-acting sequences responsible for this process. These sequences were isolated using a transfection assay wherein coding sequences for β-galactosidase were fused to sequences derived from the chicken β-cytoplasmic actin cDNA. The percent of cells which showed peripheral localization of the enzymatic activity was quantitatively monitored and provided a rigorous evaluation of each construct. Statistically, significant differences in the localization capacity of various segments of the β-actin cDNA could be distinguished by this approach. Importantly, anti-sense oligonucleotides complementary to the β-actin RNA zipcode confirmed the physiological importance of this sequence and suggested a role of β-actin mRNA localization in cell morphology.

Plasmid Constructions

Twelve day-old chicken embryonic fibroblasts (CEF) were prepared using standard techniques and cultured on gelatin-coated coverslips as previously described (Lawrence et al., 1989; Sundell and Singer, 1990). The transfection, staining, and statistical analysis were done as previously described (Kislauskis et al., 1993). After transfection, cells on coverslips were washed with PBS solution, fixed for 10 min at room temperature in 4% paraformaldehyde in PBS/5% MgCl₂, rinsed in PBS to be stored in 70% ethanol at 4°C. For methods where enzyme activity and the reporter mRNA were detected simultaneously, nick-translation probes were generated using standard procedures (Lawrence and Singer, 1989). To detect endogenous actin mRNAs, coverslips were hydrated in 20 ng of nick-translated digoxigenin-β-actin cDNA sequences 95-1477 (Sundell and Singer, 1990). To detect Lac Z reporter mRNAs, each coverslip was hybridized to 20 ng of digoxigenin-labeled, nick-translated RSVβgal plasmid overnight at 37°C. Anti-digoxigenin conjugated to alkaline phosphatase was diluted 1:250 in PBS containing 2 mg/ml BSA (Boehringer Mannheim Corp., Indianapolis, IN). Alternatively, a double-label in situ hybridization procedure, a primary antibody anti-digoxigenin HRP to detect endogenous actin mRNA (Boehringer Mannheim) at a 1:250 dilution in PBS plus 0.2% BSA was incubated for 30 min at 37°C, washed, subsequently stained with diaminobenzidine (DAB), and amplified by silver enhancement using the AMP B Silver Enhancement Kit (DIGENE Diagnostics Inc., Silver Spring, MD). This was used simultaneously with the β-galactosidase reaction to identify the distribution of fusion transcript. Cellular actin was stained after fixation with FITC-conjugated phalloidin (Molecular Probes Inc., Eugene, OR).

Phosphorothioate Antisense Oligonucleotides

Antisense treatment was performed on CEFs grown as described above, to ~50% confluence in OPTI-MEM I medium (GIBCO BRL) containing 10% FBS. Oligonucleotides were synthesized on a DNA synthesizer model 396 (Applied BioSystems, Foster City, CA), purified through CEPACK columns (Millipore, Milford, MA), lyophilized overnight, and resuspended in DEPC-treated distilled water. Each oligonucleotide was added to the complete medium (Opti-MEM 1 supplemented with 10% FBS). Experiments which required 12-h exposure to these antisense oligonucleotides involved these three treatments, 4 h each, in 1 ml complete medium. In Fig. 4, oligo A was 5'-TGGTAAATCGGCGGCTTA which corresponded to antisense sequences from the stop codon through the first 15 nt of the 3'UTR (position 1222-1239), oligo B: 5'-TCATCACAGGGGTGTTGGTT (position 1204-1260), oligo C: 5'-CTGATCTGAGTTTTGTT (positions 1261-1278), oligo D: 5'-ATCCTGTCAGGCGG (positions 1279-1297), oligo E: 5'-CTCGTCTTGTTT (positions 1412-1432), and oligo F: 5'-ACAAATGACATGCGTGC (positions 1433-1453). Oligo C complements oligo C and corresponded to the sense (mRNA) sequence (positions 1261-1278).

RNA and Protein Electrophoresis

Total RNA was extracted from CEFs as previously described (TRI Reagent, Cincinnati, OH), and resolved in a 1% agarose/2/2 M formaldehyde gel before blotting onto ZetaProbe (BioRad Labs., Hercules, CA). One blot was hybridized overnight to 32P-labeled antisense riboprobe generated from the human GAPDH cDNA insert (Clonetech, Palo Alto, CA) at 37°C, washed, and exposed 20 min to film without a screen. Subsequently, chemiluminescence was performed to detect actin mRNA on the same blot. Initially the strip was stripped in 5 mM EDTA for 50 min in boiling water, and then pre-hybridized at 37°C in 50% formamide, 5× SSC, 0.5% SDS, 5× Denhardt's, and 50 mM NaPO₄ for 2 h. Digoxigenin-labeled-actin probe (250 ng) were added and hybridized at 37°C for 12 h in the prehybridization solution plus 1% dextran sulfate. The filter was washed as described above, and then in 5× blocking Reagent in 150 mM NaCl/50 mM Tris pH 7.5 (buffer 1, Boehringer Mannheim) for 30 min at room temperature (RT). Anti-digoxigenin conjugated to alkaline phosphatase (Boehringer Mannheim) was diluted (1:2,500) in 20 ml of blocking buffer and incubated for 30 min at RT. The unbound antibody was washed from the filter, and the filter was rinsed in buffer 3 without MgCl₂, and chemiluminescent substrate was diluted (ImmunoLite Assay Kit, Bioread Labs.), and the blot was incubated in the presence of the substrate for 5 min at RT before exposing it to film at RT. A separate preparation of total RNA from similarly treated CEFs was blotted as above and probed with gel-isolated, random-primed, β-actin 3'UTR sequence (positions 1193-1814) with specific activity of 5 × 10⁶ cpm/ml (Boehringer Mannheim), was washed as described above, and exposed to film for 1 h at -80°C.

CEF were labeled after a 12-h treatment with the various oligonucleotides for 30 min with 150 μCi/ml 32P [γ-32P]methionine (Amersham Corp., Arlington Heights, IL) in MEM supplemented with L-leucine and L-lysine.
(GIBCO BRL). Equal TCA-precipitable counts were electrophoresed through 10% SDS-polyacrylamide gel using standard procedures (SEQUAGEL, National Diagnostics, Atlanta, GA). The gel was fixed and silver stained using Silver Stain plus kit (BioRad Labs.), and then dried, treated with Amplify (Amersham Corp.) for 30 min, and exposed to film at -70°C with enhancing screens. Immunoprecipitation of β-actin involved incubation with saturating concentration of precleared H2 anti-β-actin antisera (10 μl) (Oney et al., 1987) at 4°C overnight on orbital rocker before the addition of 75 μl protein G-Sepharose (Sigma Chem. Co., St. Louis, MO) and an additional 2-h incubation at 4°C. After a brief spin at 14,000 rpm, the pellet was resuspended in 2x sample buffer, boiled for 2 min, and loaded as above.

Results

Structural Properties of the β-Actin RNA Zipcode

Cis-acting RNA determinants responsible for targeting β-actin mRNA to the cell periphery were shown to be capable of conferring peripheral localization to a reporter mRNA encoding β-galactosidase in a transient assay (Kislauskis et al., 1993). To map those sequences to their minimum length, various portions of the chicken β-cytoplasmic actin cDNA were inserted into the polylinker between the E. coli LacZ gene and the SV40 3UTR, in the vector RSVβgal (Fig. 1 A). After a transient expression period, CEFs were fixed and stained by a brief (5-15 min) incubation with a chromogenic β-galactosidase substrate, X-gal. The transfection protocol did not affect the localized distribution of endogenous actin mRNA (Fig. 1 B). Our "zipcode trap" assay for the presence of zipcode sequences in each construct relied on a significant increase in the number of transfectants with reaction product (blue stain) localized to the cell periphery (Fig. 1 D) vs those with blue stain distributed throughout the cytoplasm (Fig. 1 C).

In nearly all cells (94%) transfected with the vector alone (Fig. 1 C), β-galactosidase activity (blue staining) was found to be nonlocalized, throughout the cytoplasm. In marked contrast, a significant number of transfectants (33%), expressing reporter transcripts fused to the entire chicken actin cDNA (∼1.8 kb), showed blue staining prominently in the peripheral cytoplasm (Fig. 1 D). This magnitude was similar to the endogenous level of actin mRNA localization (Kislauskis et al., 1993; Latham et al., 1994). In situ hybridization was performed using probes specific for β-galactosidase coding sequences after staining with X-gal to reveal that the distribution of reporter RNA correlated with the distribution of β-galactosidase activity in the same transfecnt. Thus, in-

Figure 1. Zipcode Trap expression vector and representative CEF transfectants. (A) Schematic of RSVβgal plasmid vector and the site of insertion of actin sequences. Actin sequences are inserted downstream of the β-galactosidase termination codon, thereby extending the 3'UTR of the reporter mRNA. (B) Endogenous actin mRNA (purple) in a CEF exposed to transfection conditions. Detection was by a digoxigenin-labeled cDNA probe for β-actin mRNA sequences. Actin localization to the leading lamellae, in 40-60% of CEFs, was unaffected by the transfection protocol. Transfected cells are represented in C and D. The distribution of β-galactosidase activity (blue staining) and/or reporter mRNA evident in transfecnt after the transient expression of vector (C) or the reporter gene fused to the full-length β-actin mRNA (D). Bars: (B) 10 μm; (C and D) 20 μm.
tracellular β-galactosidase activity was an accurate indicator of the LacZ mRNA distribution in our transient assay. These data provided a statistically significant basis for assessing RNA localization sequences. In addition, the enzymatic assay was more rapid and convenient than in situ hybridization.

Using the spatial expression characteristics of these chimeric gene products, a 54-nt zipcode was mapped to the 3'UTR of β-actin just proximal to the coding region. A series of 3'-deletions and subcloned fragments of the β-actin cDNA were evaluated for their ability to target β-galactosidase activity to the leading edge of transfected CEFs (Fig. 2). A significant 5.8-fold (32.6%/5.6%) increase in localization over the vector was found using the full-length β-actin insert fused to β-galactosidase (p < 0.0002). Equally significant increases in localization were found with two 3'-exonuclease deletion constructions, construct B with 458 nt of 3'UTR deleted and construct C with 536 nt deleted. A 438-bp fragment containing 45 nt of coding sequence through 440 nt of the 3'UTR (construct D) also localized as well (6.9-fold). In construct C, all but the first 54 nt of the 591 nt 3'UTR were removed from the full-length β-actin cDNA; further deletion of the entire 3'UTR plus 20 nt of coding region (construct E) resulted in a level of activity indistinguishable from the vector control (p = 1.0). When evaluated separately, the last 20 nt of β-actin coding region and its entire 3'UTR (construct F) was sufficient to target β-galactosidase activity to the peripheral cytoplasm as well as the full-length actin cDNA and highly significant relative to the vector control (p < 0.0002). Overall, these results indicated that the zipcode existed proximal to the stop codon.

Three synthetic oligonucleotides were evaluated: the putative zipcode within the first 54 nt of the 3'UTR including the stop codon (construct G), and sequences flanking this putative zipcode in the coding region (construct H) and in the 3'UTR (construct I). Peripheral localization activity directed by construct G was comparable to the full-length cDNA (p < 0.0002). The activities of the flanking regions (constructs H and I) were not significantly different from either the vector alone or the 5'UTR plus coding region (p > 0.99 in all cases). Therefore, the first 54 nt of the β-actin 3'UTR was sufficient to target a heterologous mRNA to the peripheral cytoplasm.

To determine if the zipcode was the sole element necessary for localization, it was deleted from full-length β-actin cDNA (construct J). Its activity significantly reduced, but did not eliminate, localization activity relative to the full-length insert. Activity was contained within the remaining 3'UTR fragment (construct K) and was significant relative to the vector (p < 0.24). Within that segment, homologies with the 54-nt zipcode were evident in a 43-nt sequence (construct L) which contained half the localization activity of the 54-nt zipcode (17 vs 33%) and was significant relative to the vector (p < 0.79).

To ascertain whether the 54- and 43-nt segments were the

| CONSTRUCT | INSERT | LOCALIZATION ACTIVITY | PERCENT (S.D.) |
|-----------|--------|-----------------------|---------------|
| A         | no insert | -                    | 5.6 (+/-2.2) |

Figure 2. Localization determinants mapped to a 54-nt and a 43-nt segment of the β-actin 3'UTR. Schematic of a series of restricted β-actin cDNA sequences inserted into the RSVβgal plasmid 3' poly linker. Designated schematically are vector polylinker sequences (solid filled box), β-actin coding sequences (diagonally hatched box), and β-actin 3'UTR sequences (solid line). Each construct (A-N) was evaluated in 3-20 independent experiments with 300 to several thousand transfected (blue) cells counted per experiment. Transfectants were scored as localized or nonlocalized based on whether the cytoplasmic distribution of blue staining was peripheral or nonlocalized. The percent of transflectants with peripheral blue staining was calculated for each experiment. The activity was summarized for each construct based on statistical significance: ++ >27%; + 14-28%; +/- 10-14%; and - <10%. The position of the 54-nt zipcode and 43-nt segments within the 3'UTR are indicated with vertical dotted lines.
sole localization determinants, both were deleted from the full-length insert (construct M). This double mutant (construct M) was incapable of localizing β-galactosidase, and its activity was indistinguishable from the vector alone. Therefore, only these two segments function to target β-actin mRNA to the peripheral cytoplasm. Because the first 54 nt of the 3'UTR contained activity comparable to the entire β-actin cDNA, we refer to it as the "peripheral RNA zipcode". The 43-nt segment with submaximal activity and homology to the peripheral RNA zipfile is composed of "zipcode elements."

To test orientation dependence, the 54-nt zipcode was inverted (construct N). Inversion of the zipcode reduced the percent localized from 33 to 11% of the transfectants, a level which was not significantly different from the vector ($p > 0.81$). To address the question of position dependence, the zipcode was inserted into the reporter 5'UTR. Because of a shift in the reading frame, β-galactosidase was not translated when the zipcode (which contains an initiation codon) was inserted into the 5'UTR in the normal orientation. Localization activity in this case was evaluated by in situ hybridization. Quantitation of transfectants showed weak but significant localization activity (15%) relative to the vector alone, which was not significantly different from the vector ($p < 0.08$). To address the question of position dependence, the zipcode was inserted into the reporter 5'UTR. Because of a shift in the reading frame, β-galactosidase was not translated when the zipcode (which contains an initiation codon) was inserted into the 5'UTR in the normal orientation. Localization activity in this case was evaluated by in situ hybridization. Quantitation of transfectants showed weak but significant localization activity (15%), relative to the vector alone, which was not significantly different from the vector ($p < 0.08$).

**Fine Structure of the Zipcode**

Sequence homology between the 54- and 43-nt segments might be expected to identify the minimal zipcode sequence. Two motifs, GGACT and AATGC, are present in both segments (Fig. 3). The GGACT motif occurs at the 5'-end and the AATGC motif occurs at the 3'-end of the 54-nt zipcode. To evaluate whether the sequences between these motifs function in localization, positions 10 through 40 in the 54-nt zipcode were deleted (construct O). Deletion of those sequences reduced localization activity (20.9%), comparable to the 43-nt segment ($p = 1.0$), but significantly different from the vector alone ($p < 0.095$). This suggested that the sequences between position 10 and 40 are important for enhancing localization. Possibly two ACACCC motifs removed from the 54-nt segment (construct O) contribute to its activity. A two base deletion of the 54-nt zipcode (construct P) which removed the A and T residues adjacent the AATGC motif was tested. This resulted in reduced localization activity (16%), significantly different from the 54-nt zipcode ($p < 0.002$), indicating the importance of the 3'-motif sequence for localization.

To test the contribution of the two motifs, independently, each was synthesized as a cassette and evaluated. Remarkably, both the GGACT motif (inserted as TAAACCGGAC-TGT) and the AATGC motif (inserted as AACCCATAAATGC) were each found to contain weak localization activity (15.2 $\pm$ 2.3% and 19.3 $\pm$ 7.2%, respectively). Their activities were not significantly different from each other or the combination of the two together in construct O ($p = 1.0$ in all cases). However, localization activity of the 5' motif GGACT was slightly less significant than the 3' motif relative to the vector alone ($p < 0.129$ and $p < 0.002$, respectively). The size or number of zipcode motifs may also be important for maximal localization. To determine whether these motifs inserted as tandem repeats would function more efficiently, the vector containing three copies of the GGACT motif, in the context of the first 10 nt of the 3'UTR and stop codon, and the vector containing four copies of the AATGC motif, in the context of the last 13 nt of the zipcode, were evaluated separately. Both constructs bearing tandem copies of each motif showed enhanced localization activity. Four copies of the 3' motif (AATGC) localized almost as effectively as the entire intact zipcode (27.5 $\pm$ 1.6%), while three copies of the 5' motif (GGACT) had somewhat less activity (20.7 $\pm$ 8.9%). These data indicated that the elements which comprise the entire 54-nt zipcode each contain submaximal localization activity. The weak localization activity of at least one motif in the zipcode can substitute for the activity of the entire zipcode when multimerized. The high A/C content in the 54-nt zipcode, contained within both 5' and 3' motifs, appearing as AAACC, ACACCC, or ACACAA may play a part in the mechanism of β-actin mRNA localization. The zipcode, therefore, appears to be composed of several minimal motifs, each of which adds proportionately to the localization.

**Conservation of Zipcodes**

Further insight into essential sequences required for zipcode function was revealed by comparing the chicken zipcode with the homologous region of the human β-actin cDNA. The mechanism of RNA localization, and hence the zipcode sequences, would be expected to be conserved between

---

**Figure 3.** Nucleotide sequence and positions of putative sequence elements (motifs) in the 54-nt RNA zipcode. The letter designation corresponds to the identity of constructs in Fig. 2 and in the text. (G) The first 54-nt of the chicken β-actin 3'UTR, positions 1222-1278. (O) Internal deletion of 31-nt from 54-ntzipcode which reduced its activity from ++ to +. (P) Two base internal deletion which reduced its activity from ++ to +. (L) Chicken β-actin 43-nt zipcode with + activity (positions 1412-1452). Shared sequence motifs are oriented by wedge-shaped arrowheads over each sequence, a 5' motif by a solid wedge and a 3' motif with an open wedge. Note the order of the two motifs are reversed in the 43-nt segment vs the 54-nt zipcode.
Functional Properties of the β-Actin RNA Zipcode

To confirm the role of the zipcode to localize endogenous actin mRNA, phosphorothioate-modified oligonucleotides were used as antisense to inhibit zipcode function. The effects of these modified oligonucleotides (18-mers) on actin mRNA localization and cell phenotype was assessed after a 12-h treatment. The positions and orientations relative to the β-actin RNA zipcode are diagrammed schematically (Fig. 4). Treatment with antisense oligonucleotides corresponding to zipcode sequences resulted in a suppression of β-actin mRNA localization relative to untreated CEFs, while a sequence flanking the zipcode and a sense sequence had no effect. In particular, oligo C (the 3' end of the zipcode) reduced the percent of CEFs with a peripheral distribution of actin mRNA to 21% of control. Antisense oligonucleotides A and B (the 5' two-thirds) were less effective (33 and 37% of control, respectively). Similarly, oligonucleotides complementary to the 5' half (oligo E) and 3' half (oligo F) of the 43-nt RNA zipcode element reduced localized actin mRNA (51 and 29%, respectively). The mechanism may involve sequence homologies between the zipcode elements. In striking contrast, neither the 3'UTR sequences flanking the 54-nt segment (oligo D) nor the sense strand of the most effective inhibitory probe (oligo C+) reduced actin mRNA localization relative to control, (91 and 98%, respectively). These data add strong support to the role of the RNA zipcode in endogenous β-actin mRNA localization to the cell periphery.

The effects of antisense treatment on actin mRNA distribution are illustrated (Fig. 5, left panels). A normal peripheral
distribution of actin mRNA and characteristic polarized phenotype were maintained in untreated CEFs (control) and CEFs treated with oligo C+ (zipcode sense) and oligo D (flanking the zipcode). In contrast, CEFs treated with oligo C (the 3' end of the zipcode, upper left panel) showed a non-localized, homogeneous distribution of actin mRNA and a change to a nonpolarized morphology. In addition, cells treated with oligo C became stellate in shape with collapsed lamellae and were less well spread, suggesting a reduced adhesion to the substrate. These data imply that the asymmetric distribution of actin mRNA localization may be reflected in a concomitant structural asymmetry, most likely of the actin cytoskeleton. To assess the distribution of actin filaments after incubation with the antisense oligonucleotides, CEFs were stained with phalloidin (Fig. 5; right panels). Unlike control cells and cells treated with oligo D, where actin staining is concentrated within the leading edge, and stress fibers are polarized toward the leading lamellae, CEFs treated with oligo C showed no leading edge and little actin staining at the periphery; the actin filament system was organized perinuclearly. Thus, the actin cytoskeleton reorganized after treatment with antizipcode oligo C, but not with the sense strand (oligo C+), or a flanking sequence (oligo D).

Delocalization of the mRNA by the antisense treatment may have resulted from a disruption of a specific aspect of the localization pathway, such as transport or anchoring. Alternatively, the steady state level or integrity of actin mRNA may have been affected by the treatment. To address the latter issue, Northern blot analysis was performed on total RNA extract from CEFs after each antisense oligonucleotide treatment (Fig. 6 A). Actin mRNA levels were compared directly to an internal standard, GAPDH mRNA. No substantial change in steady state levels of actin mRNA was observed (+15%) relative to the GAPDH. Moreover, the Northern analysis revealed no change in the size distribution of actin mRNA after incubation with the antisense oligonucleotides which indicate that RNase H-mediated degradation did not occur. Therefore, the inhibition of actin mRNA localization cannot be explained by an effect on mRNA stability or integrity. These conclusions were confirmed with a separate Northern blot of RNA from similarly treated CEFs probed with β-actin 3'UTR sequences showing no change in β-actin mRNA quantity or quality.

Figure 6. Antisense oligonucleotides do not destabilize steady state β-actin mRNA levels, or suppress actin protein synthesis. (A) Northern blot analyses of total RNA were extracted from control cells (dash mark) and cells treated for 12 h (three treatments, of 4 h each) with 8 μM oligo C, A, D, E, or F and probed with β-actin cDNA (upper panel) and GAPDH cDNA (middle panel). The ratio of ~1.8 kb actin mRNA signal to ~1.3 kb GAPDH mRNA in each case shows no change in actin mRNA levels resulting from the antisense treatments. Hybridization to β-actin 3'UTR sequences (lower panel) showed comparable results relative to ethidium-stained 18 S ribosomal RNA. No indication of antisense-induced RNase H activity was evident in the size distribution of actin mRNA signal in the upper and lower panels. Arrows indicate the position of 18S ribosomal RNA. (B) SDS-PAGE gel electrophoresis of total-labeled proteins extracted from control cells and cells treated for 12 h with 8 μM oligonucleotides A-D and C+, after a 30-min pulse with [35S]methionine. The relative ratio of actin (43 kD) to the 29 kD band is shown (upper panel). Quantitation relative to total protein of amounts of β-actin after immunoprecipitation with a β-actin-specific antibody is shown (lower panel). The results of both analyses indicate no appreciable effect on β-actin (43 kD) protein synthesis.
There are at least two mechanisms by which antizipcode oligonucleotides could affect actin expression, and, thereby, cell phenotype. First, inappropriately localized actin mRNA may suppress actin protein synthesis. Over the 12-h treatment, this could deplete the cellular pool of G-actin. Alternatively, nonlocalized actin mRNA could affect the site of actin protein synthesis, and consequently influence sites of actin polymerization. To distinguish between these possibilities, CEFs were treated with each oligonucleotide for 12 h, pulse-labeled with [35S]methionine, and extracted. No change in total cellular actin synthesis (<14%) relative to a 29-kD band on the autoradiogram was observed among the various antisense probes (Fig. 6 B). To address the question of whether expression of the β-actin isoform was specifically affected by this treatment, equal counts of the same extracts were immunoprecipitated using a β-actin specific antibody. Quantitation of the 43-kD β-actin band in each case relative to the untreated control extract indicated no significant effect in β-actin synthesis. Therefore, the striking change in cell phenotype that resulted from exposure to an antisense oligonucleotide (oligo C, Fig. 5, A and B) could not be due to its effect on actin synthesis per se. Rather, we conclude that the consequence of treatment with antizipcode oligonucleotides on cell phenotype resulted from a change in the site of β-actin synthesis, and, hence, the site of actin concentration within the cell. This supports the hypothesis that the RNA zipcode directs β-actin mRNA to the cell periphery where the protein synthetic apparatus can provide a compartmentalized source of G-actin to facilitate the assembly of actin filaments involved in the maintenance of cell structure, polarity, and motility.

Discussion

Three approaches were used to define cis-acting sequences in the β-actin 3'-UTR that are essential for peripheral mRNA localization. First, transiently expressed LacZ/β-actin RNA chimeras enabled identification of two short segments of 3'UTR capable of directing β-galactosidase activity to the peripheral cytoplasm. The localization activity resided in a principal RNA zipcode within the first 54 nt, and in a related but weaker secondary 43 nt sequence further downstream. Second, the homologous region of the human β-actin 3'UTR acted effectively as a zipcode in chicken cells. Conserved sequence motifs between these divergent species may therefore be functionally important. Third, the functional importance of the zipcode was confirmed using antisense oligonucleotides to the sequences predicted by chimeric genes to be essential for actin mRNA localization. Oligonucleotides complementary to portions of the 54-nt zipcode or the 43-nt segment, delocalized endogenous β-actin mRNA and altered cell morphology. Our antizipcode oligonucleotides do not appear to destabilize mRNA nor do they suppress the synthesis of actin protein relative to control oligonucleotides. We conclude that the RNA zipcode is critical to the mechanism of actin mRNA localization and for the organization of the actin cytoskeleton.

This use of antisense technology to modulate the distribution of mRNA, rather than for the purposes of inhibition of gene expression, represents a novel application. Whether other mRNAs with identical peripheral RNA zipcode motifs were affected by this antisense treatment is unknown. Functionally related mRNAs could determine cell polarity or morphology by spatial coordination of their sites of protein synthesis. Hence, interaction between cognate proteins would be facilitated by increased concentrations within the correct cytoplasmic compartment. A comparison of the β-actin localization sequence to a database (Genetics Computer Group, Madison, WI) has revealed sequence homologies with mRNAs encoding actin-associated proteins, including fibrin, villin, and members of the Marcks family. Whether these homologies are zipcodes remains to be determined. However, Northern blot analysis using the oligonucleotide probes indicates that hybridization is β-actin mRNA-specific (data not shown).

In general, RNA localization signals have been mapped to the 3' ends of mRNAs. For instance, sequences involved in the anterior localization of bicoid mRNA in Drosophila oocytes, originally mapped by genetic complementation to a 625-nt 3'UTR segment (Macdonald and Struhl, 1988), have recently been refined to several smaller regions, including a 50-nt segment necessary in the early stages of localization, BLE1 (Macdonald et al., 1993). Other Drosophila 3'UTR localization signals include an anterior localization signal in the zygotic K10 gene restricted to a ~1.4-kb 3' segment (Cheung et al., 1992). Posterior localization signals have been found within the ~1.7-kb segment of the maternal mRNA coding for nanos (Gavis and Lehmann, 1992), the ~1.1-kb 3'UTR of oskar (Kim-Ha et al., 1993), and two closely apposed segments of 94 and 87 nt within the cyclin B (Dalby and Glover, 1993). In blastoderm embryos, apical localization signals have been identified on zygotic pair-rule transcripts with the shortest occurring within the last 124 nt of the even-skipped gene (Davis and Ish-Horowicz, 1992). In Xenopus oocytes, a vegetal pole localization signal has been restricted to a 340-nt region of the maternal vg-1 mRNA (Mowry and Melton, 1992). To resolve details of the mechanism of RNA localization in each case will require more accurately delimited zipcode sequences.

Our analyses indicate that functional components of the β-actin mRNA zipcode are quite diminutive in size. Deletions within the 54-nt sequence reduced but did not eliminate localization activity (data not shown). These observations, and the work of others, indicate that RNA localization signals have size constraints and are multicomponent in their organization. The potential of 3'UTR sequences to form multiple stem-loops (e.g., Drosophila Bicoid genes) has suggested that localization may involve RNA secondary structure (Macdonald, 1990). Such a model would predict that separate 3' elements hybridize to form a secondary structure necessary to interact with the localization machinery. Both bicoid and oskar mRNA localization sequences appear to be composed of multiple interspersed segments which could function at different steps in the process (Kim-Ha et al., 1993; Macdonald et al., 1993). The identification of at least two localization elements in the β-actin mRNA supports the principle of redundancy of zipcode elements in the 3'UTR, but the sequences show little, if any, complementarity, and do not support the role of secondary structure in RNA localization. This is unusual as most functional RNA elements form secondary structure (Klausner et al., 1993).

In some cases, differential RNA localization might be explained by a translational control mechanism. For instance, repression of translation of two morphogens, bicoid and...
hunchback, requires nanos (nos) protein, occurs through a small 3'UTR sequence called nos-responsive element (NRE), which may act to destabilize NRE containing RNAs (Wharton and Struhl, 1991). The NRE appears to be necessary for the translational control but not localization of cyclin B mRNA at the posterior pole (Dalby and Glover, 1993). A distinction between localization determinants and NREs also remains unclear for the C. elegans glp-1 gene. Expression of GLP-1 protein is spatially and temporally regulated, is localized to anterior blastomeres, and appears to be important for the specification of several anterior cell fates. Recently, NRE-like motifs have been identified within a 61-nt segment of glp-1 3'-untranslated region critical for the spatial control of GLP-1 expression, and not within the adjacent uridine-rich 125 nt critical for its temporal control (Evans et al., 1994).

The possibility that the β-actin RNA zipcode functions in this manner, as a temporal control region, appears unlikely based on the fact that β-galactosidase expression was not appreciably reduced or increased between the various constructs, nor were there any significant differences in transfection efficiency of the various constructs. Thus, there can be no gross differences in reporter RNA stability. For similar reasons, translational efficiency of the β-galactosidase mRNA chimeras does not appear to be a factor in localization.

That components of the mechanism of mRNA localization may be highly conserved throughout evolution is not entirely surprising. The mechanism of mRNA localization is dependent on cytoskeletal filaments (Pokrywka and Stephenson, 1991; Sundell and Singer, 1991; Theurkauf et al., 1992; Yisraeli et al., 1990). Actin and tubulin, themselves, are highly conserved evolutionarily. It is possible that homologous elements within zipcodes form binding sites for conserved proteins involved in mRNA transport or the anchoring. Factors which recognize conserved mRNA sequences as well as conserved cytoskeletal proteins may include some of the well-known cytoskeletal-associated proteins. These cytoskeletal and cytoskeletal-associated proteins are highly conserved even in yeast (Drubin, 1990; Drubin et al., 1992) and would be expected to be involved in some part of the mechanism of RNA localization including sequence recognition, protein binding, and ultimately transport and anchoring. Further information will require biochemical and genetic characterization of cellular factors which bind specifically to the zipcode sequences.

In motile cells, such as CEFs and myoblasts, β-actin isoform and its mRNA predominates in the periphery of the cell, compared to other actin isoforms which are perinuclear (Hill and Gunning, 1993; Hooick et al., 1991; Kiszalskis et al., 1993). Cell morphology may result from the differences in where each isoform is synthesized. For instance, deletion of the 3'UTR of γ-actin results in changes in myoblast morphology (Lloyd and Gunning, 1993). Our data suggest a relationship between β-actin mRNA localization and the disposition of actin filaments in these motile cells. The consequence of delocalizing β-actin mRNA therefore appears to be a disruption in the asymmetric supply of β-actin within the leading lamellae, possibly essential for the maintenance of cell polarity.

Finally, the work further supports the role of the 3'UTR as a repository of regulatory elements (Jackson, 1993). RNA zipcodes can be included as one of multiple cis-regulatory signals in the 3'UTR, including those that control translation (Peltz and Jacobson, 1992) or mRNA stability (Hale et al., 1992). This work also provides a mechanistic basis for the significance of 3'UTR sequences in determining cell differentiation and behavior (Rastinejad and Blau, 1993; Rastinejad et al., 1993). RNA zipcodes add another dimension to these controls of gene expression in the cytoplasm.

We thank our colleagues Drs. J. M. Mathys, A. Ross, and M. Rosbash, and A. Jacobson for their editorial comments; Zhi-wen Zhang for her technical assistance early in the project; and Dr. J. Bulinski for donating the actin antibodies used in these experiments.

A portion of this work was presented at the American Society of Cell Biology, Kiszalski, E. H., and R. H. Singer. 1991. J. Cell Biol 115:158a. This work was supported by National Institutes of Health grants AR41480 and HD18066 to R. H. Singer, and a post-doctoral fellowship from the Muscular Dystrophy Association to E. H. Kiszalski.

Received for publication 20 April 1994 and in revised form 12 July 1994.
