Low-frequency quasilocalized modes of amorphous glass appear to exhibit universal density of states, depending on the frequencies as \(D(\omega) \sim \omega^4\). To date, various models of glass formers with short-range binary interaction and network glass with both binary and ternary interactions were shown to conform with this law. In this paper, we examine granular amorphous solids with long-range electrostatic interactions and find that they exhibit the same law. To rationalize this wide universality class, we return to a model proposed by Gurevich, Parshin, and Schober (GPS) [Phys. Rev. B 67, 094203 (2003)] and analyze its predictions for interaction laws with varying spatial decay, exploring this wider-than-expected universality class. Numerical and analytic results are provided for both the actual system with long-range interaction and for the GPS model.

I. INTRODUCTION

It has been known for more than 30 years now [1–7] that low-frequency vibrational modes in amorphous glassy systems are expected to present a density of states (DOS) \(D(\omega)\) with a universal dependence on the frequency \(\omega\), i.e.,

\[ D(\omega) \sim \omega^4. \]  

The direct verification of this prediction is not always straightforward, since the modes which are expected to exhibit this universal scaling are quasilocalized modes (QLMs) that in large systems hybridize strongly with low-frequency delocalized elastic extended modes. The latter modes have another universal form; their density of states depends on frequency like \(\omega^{d-1}\) where \(d\) is the spatial dimension. To observe the universal law Eq. (1), one needs to disentangle these different types of modes. Numerical simulations are ideal for this purpose since by necessity they are limited to relatively small systems in which the (Debye) delocalized modes have a lower cutoff, exposing cleanly the QLM with their universal density of states Eq. (1). In fact, the lowest Debye mode is expected to have a frequency of the order of \(2\pi c/L\), where \(c\) is the speed of sound and \(L\) is the system size. Thus, in smaller systems, the lower cutoff of the Debye modes is pushed up. In recent literature, there were a number of direct verifications of this law, using numerical simulations of glass formers with binary interactions [8–14] and also more recently in models of silica glass with binary and ternary interactions [15,16].

The aim of this paper is to examine how long-ranged interactions effect the density of states. To this aim, we return to a model studied recently of charged disks and spheres in two and three dimensions, respectively [17]. On the face of it, the existence of long-ranged interactions could introduce strong deviations from the universal law Eq. (1). To our surprise, it turned out that the scaling law Eq. (1) is very robust, and the addition of long-ranged interactions did not alter it. To understand this, we return to the very interesting theory offered by Gurevich, Parshin, and Schober (GPS) [5], which over 20 years expounded their understanding of the origin of the scaling law Eq. (1). In the third section of this paper, we paraphrase their derivation, extending it to interaction laws that were not treated by these authors. We make a special attempt to stress the main assumptions and approximations that underlie the proposed universality. In particular, we seek interactions and parameters that should, according to the theoretical analysis, lead to a failure of Eq. (1) to further clarify when and where the universality is expected to hold. We find that in fact the law Eq. (1) is very robust, even when the conditions for the existence of the theory are not available. In some sense, the universality of Eq. (1) is broader than one could anticipate.

The structure of this paper is as follows: In Sec. II we discuss the model of charged disks or spheres and present the numerical results for the density of states. In Sec. III, we offer a review of the theory of Refs. [3–6] with strong emphasis on the assumptions and approximations made. In Sec. IV, we examine the GPS model with various laws of interaction, with a stringent test on the applicability of the assumptions in the theory. A summary and conclusions are offered in Sec. V.

II. CHARGED GRANULAR MODEL

A. Model properties

To examine the density of states in charged compressed granular media, we study a model consisting of a 50-50 mixture of \(N\) frictionless two-dimensional disks or three-dimensional spheres with diameters \(R_1 = 1.0\) and \(R_2 = 1.4\), respectively. Below, all the lengths are measured in the unit of \(R_1\). Half of the smaller particles are positively charged at the center of mass with a charge \(+q\) and the other half...
are negatively charged with a charge $-q$. The same is true for the large ones. The particles are placed randomly inside a two-dimensional or three-dimensional box such that there is no overlap between two particles. Molecular dynamics is then used to equilibrate the system. During this equilibration, one adds a damping term $-\kappa_r \dot{r}_i$ to each of the equations of motion. Once equilibrated, the system is compressed in small steps to achieve a required packing fraction $\phi > \phi_1$, with the above-mentioned damping to equilibrate the system after each step. The value of $\phi_j \approx 0.843$ in 2D and 0.639 in 3D, being the jamming packing fraction at zero temperature (for uncharged systems). The result of this procedure is an equilibrated amorphous solid that is charge-neutral. The simulation presented below employs periodic boundary conditions, the total number of particles is $N = 600, 1000, 2000$, and 8000 in 2D and $N = 3600, 4500$, and 5500 in 3D. In all cases, $\phi = 0.90$ in 2D and $\phi = 0.67$ in 3D.

The short-ranged forces between two overlapping disks are Hertzian elastic. The potential for these forces is given by [18]

$$\Phi_{\text{elas}}(r_{ij}) = \frac{2}{5} K_n \sqrt{R_{\text{dis}}(R_{ij} - r_{ij})^{5/2}}. \quad (2)$$

Here, $K_n = 20,000$ is an elastic constant. Denoting the centers of mass of the $i$th and $j$th disk as $r_i$ and $r_j$, then $r_{ij} = |r_i - r_j|$, $R_{ij} = (R_i + R_j)/2$ and $R_{\text{dis}} = 0.5R_i R_j/(R_i + R_j)$.

Apart from the elastic force, grains interact via long-ranged electrostatic forces. If $q_i$ and $q_j$ are the charges in the $i$th and $j$th grains, the electrostatic interaction potential is given, in Gaussian units, by

$$V_{\text{elec}}(r_{ij}) = \frac{q_i q_j}{r_{ij}}. \quad (3)$$

In our simulation, we use units of charge such that $q_i \equiv \pm 1$. The electrostatic interaction is of course long ranged. However, it has been shown [19,20] that in an amorphous mixture of randomly distributed charged grains, one can use the damped-truncated Coulomb potential as given by

$$V_{\text{elec}}(r_{ij}) = q_i q_j \left[ \text{erfc}(\alpha r_{ij}) - \frac{\text{erfc}(\alpha R_c)}{R_c} \right], \quad r_{ij} \leq R_c, \quad (4)$$

with $R_c$ being the cutoff scale of electric interaction, with $R_c = 7.5$ in three dimensions and 12.5 in two dimensions. Here erfc$(x)$ is the complementary error function, $\alpha = 0.15$ is the damping factor of the electrostatic interaction due to screening. Below we employ the Hessian matrix, which is the second derivative of the potential with respect to coordinates. We therefore smooth out $V_{\text{elec}}$ at $r = R_c$ to have four derivatives when $V_{\text{elec}}$ goes to zero at $r = R_c$. To this aim, we use the following form:

$$\Phi_{\text{elec}}(r_{ij}) = V_{\text{elec}}(r_{ij}) - \sum_{n=1}^{4} \frac{(r_{ij} - R_c)^n}{n!} \frac{d^n V_{\text{elec}}}{dr_{ij}^n} \bigg|_{r_{ij} = R_c}. \quad (5)$$

At this point, we should add that we have checked the sensitivity of our numerical results to the choice of $R_c$. The qualitative nature of the results did not change when $R_c$ was chosen larger, but the numerical effort was much increased.

The total binary potential $\Phi(r_{ij})$ is therefore

$$\Phi(r_{ij}) = \Phi_{\text{elas}}(r_{ij}) + \Phi_{\text{elec}}(r_{ij}). \quad (6)$$

Finally, the Hessian matrix is given by

$$H^\alpha_{ij} = -\left( \frac{\partial^2 \Phi(r_{ij})}{\partial r_{ij}^2} - \frac{1}{r_{ij}} \frac{\partial \Phi(r_{ij})}{\partial r_{ij}} \right)n^\alpha_{ij} n^\beta_{ij} - \frac{\delta_{ij}}{r_{ij}} \frac{\partial \Phi(r_{ij})}{\partial r_{ij}}. \quad (7)$$

where $n^\alpha_{ij} = (r_{ij}^n - r_{ij}^\alpha)/r_{ij}$. The diagonal elements of the Hessian matrix read

$$H^\alpha_{ii} = -\sum_{\ell \neq i} H^\alpha_{i\ell}. \quad (8)$$

The Hessian matrix, being real and symmetric, has real eigenvalues. Besides Goldstone modes associated with continuous translational symmetries that yield two (three) zero eigenvalues in two (three) dimensions, all other eigenvalues are positive as long as the system is mechanically stable. Every eigenvalue $\lambda_i$ of the Hessian matrix is associated with a frequency

$$\omega_i \equiv \sqrt{\lambda_i}. \quad (9)$$

The density of states refers to the probability distribution function (PDF) $D(\omega)$ of these frequencies in the limit $N \to \infty$.

### III. THE UNIVERSALITY OF THE DENSITY OF STATES

The density of states of our charge-neutral system is computed in both two and three dimensions for various system sizes. It is important to ascertain the convergence of the density of states since one observes strong finite-size effects, besides the obvious remark that a “density” exists only in the limit $N \to \infty$ [21]. In Figs. 1 and 2, we present the low-end (small frequency) regime of the density of states of the model discussed above for four (three) system sizes in two (three) dimensions.

The conclusion that we draw is quite obvious, i.e., that the universality class of Eq. (1) includes the present system despite the long-range interactions, in both two and three dimensions. As seen in other cases, there is a system-size dependence, with the slope approaching 4 when the system size increases [21]. The price is that for larger systems Debye modes and hybridization penetrate lower frequencies [8], shortening the regime of the universal power law, as can be seen in Fig. 2. It is important to realize that the modes that participate in the scaling law Eq. (1) are all QLMs, rather than extended Debye modes. To exemplify this, we present in Figs. 3 and 4 representative eigenfunctions whose eigenvalues are in the range of the universal scaling law. These are obviously not extended modes, as one can also check by evaluating their participation ratio. To rationalize the width of the universality class, we return now to the theory proposed in Refs. [3–6].
FIG. 1. The low (small-frequency) tail of the density of states of the two-dimensional model of charged disks discussed in Sec. II for four different system sizes, i.e., \( N = 600, 1000, 2000, \) and \( 8000 \) in panels (a)–(d), respectively. In all cases, we employed 10 000 independent configurations. The lines are best fits to the small-frequency tail of the DOS. We conclude from this data that the density of states converges to the universal law Eq. (1).

The theory is based on the notion that the normal modes of the Hessian can be represented as a collection of interacting oscillators. Once this is accepted, the derivation has two essential parts. First, a complete reconstruction of the “bare” vibrational DOS below some frequency \( \omega_c \) takes place, proportional to the strength of the elastic interaction between these oscillators. This first reconstruction is independent of the bare DOS \( g_0(\omega) \), subject to conditions on \( g_0 \) that are exposed below. This first reconstruction leads to a density of states that is linear in \( \omega_c \),

\[
g_1(\omega) = C\omega, \tag{10}
\]
with effective masses $M_1$ and $M_2$ and harmonic frequencies $\omega_1 \ll \omega_c$ and $\omega_2 \gg \omega_c$, interacting via an interaction $I_{12}$ due to an elastic field. This leads to a potential

$$U(x_1, x_2) = M_1 \omega_1^2 x_1^2/2 + M_2 \omega_2^2 x_2^2/2 + I_{12} x_1 x_2. \quad (11)$$

The interaction $I_{12}$ will renormalize the frequencies to $\hat{\omega}_{1,2}^2$, where

$$\hat{\omega}_{1,2}^2 = \frac{\omega_1^2 + \omega_2^2}{2} \pm \sqrt{\left(\frac{\omega_1^2 - \omega_2^2}{2}\right)^2 + \frac{I_{12}^2}{M_1 M_2}}. \quad (12)$$

From Eq. (12), we see that the smaller frequency $\hat{\omega}_1$ becomes zero and an instability occurs when $I > I_c$, where

$$I_c = \omega_1 \omega_2 \sqrt{M_1 M_2}. \quad (13)$$

From Eq. (13), we can now estimate $\omega_c$ as follows. It is defined as the maximum frequency that can be destabilized by the interaction $I$. Using $M_1 \sim M_2 \sim M$, $\omega_1 \approx \omega_c$, and $\omega_2 \sim \omega_{\text{Debye}}$ in Eq. (13), we find

$$\omega_c \approx \frac{I_c}{M \omega_{\text{Debye}}} \ll \omega_{\text{Debye}}. \quad (14)$$

For $I_{12} = I < I_c$, the smaller frequency approaches zero as

$$|\hat{\omega}_1| = \omega_1 \sqrt{1 - (I/I_c)^2}. \quad (15)$$

Consider now a stable collection of oscillators with a density of such low-frequency oscillators embedded in a sea of high-energy oscillators. In other words, we assume that if there were unstable oscillators with $I > I_c$, these were already reorganized when the system was equilibrated by energy minimization. Using Eq. (15), we can now write down a general expression for the reconstructed DOS of an initial DOS $g_0(\omega_1)$ due to a quenched distribution $P(I)$ of forces $I$ as

$$g_1(\omega) = \int d\omega_1 g_0(\omega_1) \int_0^{I_c} dIP(I) \delta(\omega - \omega_1 \sqrt{1 - (I/I_c)^2}). \quad (16)$$

To proceed we will assume that the distribution $P(I)$ is smooth and nonsingular at the vicinity of $I = I_c$. Performing the $I$ integration over the delta function, we end up with the expression

$$g_1(\omega) = I_c \omega \int d\omega_1 g_0(\omega_1) \frac{P(I_c \sqrt{1 - \omega^2/\omega_c^2})}{\omega_c^2 \sqrt{1 - \omega^2/\omega_c^2}}. \quad (17)$$

If we now take the $\omega \to 0$ of Eq. (17), we find

$$g_1(\omega) = I_c P(I_c) \omega \int d\omega_1 \frac{g_0(\omega_1)}{\omega_1}. \quad (18)$$

Looking at Eq. (18), we see that

$$g_1(\omega) \to C \omega \quad \text{as} \quad \omega \to 0, \quad (19)$$

with

$$C = I_c P(I_c) \int d\omega_1 \frac{g_0(\omega_1)}{\omega_1^2}, \quad (20)$$

provided the integral converges.

It should be stressed here that it is not obvious what the functional form $g_0$ is for a given example of amorphous
solid. If we take \(g_0(\omega_0) \approx g_{\text{Debye}}(\omega_0) \sim \omega_0^{d-1}\), we see that this integral converges for \(d > 2\), but for \(d = 2\) there would exist logarithmic corrections to the integral. There is no reason, however, to assume that the bare density of the QLMs is the same as the Debye modes which are extended. So we need here to continue by faith, assuming that the integral converges. Then there is a universal behavior \(g_1(\omega) \sim \omega\) though \(C\) is not universal. We will show below (cf. Sec. IV) a case where this first reconstruction does not apply because \(g_0\) is chosen such that the integral in Eq. (20) does not converge.

Another source of worry can arise if the distribution function \(P(I)\) were not benign in the vicinity of \(I_c\). For example, imagine that in the vicinity of \(I_c\), \(P(I) \sim (I_c - I)^\beta\). In that case, we could return to the analysis described above and find that

\[
g_1(\omega) \propto \omega^{1+2\beta}, \quad \text{if } P(I) \propto (I_c - I)^\beta.
\]

Since we have no control at this point on the PDF of the interactions \(I_{ij}\) we should bare in mind that this, and other possibilities that are not treated here explicitly can bust the first reconstruction to Eq. (19).

B. Second reconstruction

The first reconstruction discussed above pertains to frequencies smaller than some cutoff frequency \(\omega_c\). This second reconstruction mainly effects the DOS at frequencies \(\omega \ll \omega_c\), where \(D(\omega) \sim \omega^4\).

The second reconstruction comes about due to a further interaction between the oscillators which we have not taken into account so far. The low- frequency QLMs, displaced from their equilibrium positions, create random quenched static forces \(f_i\) on each QLM. The force \(f_i\) exerted on the \(i\)th oscillator by the other \(j\) oscillators is

\[
f_i = \sum_j J_{ij} x_{j0}.
\]

These forces have some distribution \(P(f)\). In the purely harmonic case, these linear forces would not affect the frequencies. Anharmonicity, however, renormalizes the low-frequency part of the spectrum.

Consider an anharmonic oscillator under the action of a random static force \(f\) given by the potential

\[
V(x) = M\omega_1^2 x^2/2 + Ax^4/4 - fx. \quad (23)
\]

The force \(f\) then shifts the equilibrium position from \(x = 0\) to \(x = x_0\), given by

\[
Ax_0^3 + M\omega_1^2 x_0 - f = 0, \quad (24)
\]

where the oscillator now has a new harmonic frequency given by \(M\omega_{\text{new}}^2 = d^2V(x)/dx^2|_{x=x_0}\) or

\[
\omega_{\text{new}}^2 = \omega_1^2 + 3Ax_0^2/M. \quad (25)
\]

Now given \(g_1(\omega)\) by Eq. (10) and a distribution function for the random frequencies \(P(f)\), then the renormalized DOS is given by

\[
D(\omega) = \int_0^\omega g_1(\omega)d\omega \int_{-\infty}^\infty df P(f)\delta(\omega - \omega_{\text{new}}). \quad (26)
\]

We note that because of the Dirac delta function in the second integral, only values of the force \(f\) where \(\omega - \omega_{\text{new}}(\omega_1, f) = 0\) will contribute to the integral. We can find an expression for \(\omega_{\text{new}}(\omega_1, f)\) as follows. First, from Eq. (24) for small \(f\), we find \(x_0 \approx f/(M\omega_1^2)\). If we substitute this form into Eq. (25), we find

\[
\omega_{\text{new}}(\omega_1, f) = \sqrt{\omega_1^2 + \frac{3Af^2}{M^3\omega_1^4}} > \omega_1. \quad (27)
\]

and write Eq. (26) more explicitly as

\[
D(\omega) = \int_0^\omega g_1(\omega)d\omega \int_{-\infty}^\infty df P(f)\delta(\omega - \omega_{\text{new}}(\omega_1, f)). \quad (28)
\]

The upper limit of the first \(\omega\) integral can be taken as \(\omega\), using our knowledge that \(\omega_{\text{new}}(\omega_1, f) > \omega_1\) and consequently when \(\omega_1 > \omega\), \(\omega_{\text{new}}(\omega_1, f)\) must obey the inequality \(\omega_{\text{new}}(\omega_1, f) > \omega\) and therefore cannot contribute to the \(\delta(\omega - \omega_{\text{new}}(\omega_1, f))\) integration term.

To perform this double integral let us first define a force \(f_0\) by

\[
\omega_{\text{new}}(\omega_1, f_0) = \omega, \quad (29)
\]

and then expand

\[
\omega_{\text{new}}(\omega_1, f) \approx \omega_{\text{new}}(\omega_1, f_0) + \frac{\partial \omega_{\text{new}}}{\partial f} \bigg|_{f=f_0} (f - f_0), \quad \omega_1 > \omega_1, \quad (30)
\]

Using Eq. (29), we can now rewrite Eq. (16) as

\[
D(\omega) = \int_0^\omega g_1(\omega_1)d\omega_1 \int_{-\infty}^\infty df P(f)\delta\left(\frac{\partial \omega_{\text{new}}}{\partial f} \bigg|_{f=f_0} (f - f_0)\right). \quad (31)
\]

We can perform this integral exactly and find

\[
D(\omega) = \int_0^\omega g_1(\omega_1)d\omega_1 \frac{P(f_0(\omega_1, \omega_1))}{|\partial \omega_{\text{new}}/\partial f|_{f=f_0}}. \quad (32)
\]

Combining Eq. (29) and Eq. (27), we then find an explicit form for \(f_0(\omega_1, \omega)\), namely,

\[
f_0(\omega_1, \omega) = \sqrt{(\omega^2 - \omega_1^2)^2 + \frac{3M^3\omega_1^4}{4A^4}}. \quad (33)
\]

Recall that this is the force that contributes maximally to the DOS. Note also that over the whole range of the \(\omega_1\) integration, \(\omega^2 - \omega_1^2 > 0\) and \(f_0(\omega_1, \omega)\) given by Eq. (33) is real.

We can also calculate \(|\partial \omega_{\text{new}}/\partial f|^{-1}\) from Eq. (27) and find

\[
|\partial \omega_{\text{new}}/\partial f|^{-1} \approx \frac{M^3\omega_1^4}{3A^4}\left[\frac{1}{\omega_1^2} + \frac{3Af^2}{M^3\omega_1^4}\right]. \quad (34)
\]

To complete the calculation, we need the functional form of \(P(f)\) that is so far not specified.

C. The functional form of \(P(f)\)

The distribution that we are seeking pertains to the forces that arise due to the interaction between our oscillators, displacing the low-frequency QLMs from their equilibrium positions by amounts \(x_0\). As a consequence, they create random quenched static strains \(f_i\) on each QLM due to similar
displacements \( x_{j0} \) of the other oscillators. Thus the force \( f_i \) exerted on the \( i \)th oscillator by the other \( j \) oscillators is of the form Eq. (22). Note we have chosen to treat the displacements and forces here as scalars for simplicity. More accurately, we should treat both the displacements \( x_{j0}^a \) and the forces \( f_{i}^a \) as components of a Cartesian vector and the coupling \( J_{ij}^a \) as a second-order tensor. Thus we would have \( f_{i}^a = \sum_{j} J_{ij}^\alpha x_{j0}^\beta \). But here, for simplicity, we consider these forces to be scalars with some distribution \( P(f) \).

Let us now consider \( J_{ij}^\alpha \) in more detail. We will assume there exists a spatial Poisson distributed placement of QLMs at positions \( \mathbf{r}_i \). In that case, we can write

\[
J_{ij} = y_{ij}/r_{ij}^\alpha, \tag{35}
\]

The random variable \( y_{ij} \) will take care of the relative orientation of the QLMs and have zero mean while \( |\mathbf{r}_i - \mathbf{r}_j| \) is the distance between the QLMs. The exponent \( \alpha \) depends on the nature of the interaction between the QLMs, for example, the \( \alpha = d \) for strain-induced forces between the QLMs or electrostatic dipole-dipole interactions in the case of charged granular media. But other exponents may be important depending on the nature of the granular medium. There may exist charge-charge interactions in which case \( \alpha = d - 2 \) may be a more suitable exponent. Or in the case where higher order multipole interactions occur, \( \alpha > d \) may be important. Thus, in general, we may write

\[
f_i = \sum_{j} J_{ij} x_{j0} = \sum_{j} y_{ij} x_{j0} / r_{ij}^\alpha. \tag{36}
\]

If we now examine Eq. (36) together with Eq. (24), we see that we have a many-body nonlinear problem to solve, which may be suitable for simulations (as done in Sec. IV) but well beyond analytical approach. We therefore make an unavoidable uncontrolled approximation and replace Eq. (36) by the one-body problem

\[
f_i = \sum_{j} J_{ij} x_{j0} \approx \sum_{j} z_{ij} / r_{ij}^\alpha, \tag{37}
\]

where the \( z_{ij} \) are random variables with a given \( P^* (z) \) of zero mean \( \langle z \rangle = 0 \) and a given variance \( \langle z^2 \rangle = \sigma_z^2 \). We reiterate that this step, in addition to the assumption of the existence of the integral in Eq. (20), is not guaranteed to apply to any realistic amorphous solid, and it needs to be assessed carefully in each case.

We could expect that \( \sigma_z^2 = \langle (y_{ij} x_{j0})^2 \rangle_{\gamma} \) could be estimated from simulations, but it is much better to treat the fluctuations \( \sigma_z \) as a free parameter in the theory and study how universal the predictions of the theory are with respect to changes in \( \sigma_z \). In fact we will see that, provided the fluctuations are bounded, the exact value will not be too crucial.

We also need to stress that \( P(f) \) does not follow the central limit theorem as \( N \to \infty \). As mentioned in Ref. [5], it does present strong similarities to the problem studied by Holtsmark and Chandrasekhar when studying the gravitational force fluctuations in a system of \( N \) galaxies. We shall therefore calculate \( P(f) \) as follows. In the thermodynamic limit, all QLMs \( f_i \) will have similar statistical properties. Let us now focus on one site \( i \), which we place at the origin of our coordinate system with \( f_i = f = \sum_{j} z_{ij} / r_{ij}^\alpha \). Then

\[
P(f) = \langle \delta(f - \sum_{j} z_{ij} / r_{ij}^\alpha) \rangle = \frac{1}{2\pi} \int_{-\infty}^{+\infty} d\tau \exp(i\tau f), \tag{38}
\]

where \( F(\tau) \) is the characteristic function associated with \( P(f) \), namely,

\[
F(\tau) = \langle \exp[-i\tau \sum_{j} z_{ij} / r_{ij}^\alpha] \rangle
= (1/V^N) \int d\mathbf{r}_1 \cdots d\mathbf{r}_N \int dz_1 \cdots dz_N \times P^*(z_1) \cdots P^*(z_N) \exp[-i\tau \sum_{j} z_{ij} / r_{ij}^\alpha]
= [(1/V) \int dz \int dz^* \exp[-i\tau z / r^\alpha]]^N
= [1 - (1/V) \int dz \int dz^* \exp(-i\tau z / r^\alpha)]^N. \tag{39}
\]

Equation (39) can be written in this way as all the spatial integrations \( \int d\mathbf{r}_1 \cdots d\mathbf{r}_N \) and all the random variable integrations \( \int dz_1 \cdots dz_N P^*(z_1) \cdots P^*(z_N) \) are independent of one another. Finally, in the thermodynamic limit as \( V \to \infty \), \( N \to \infty \) with \( N/V \) finite we find

\[
F(\tau) = [1 - (1/V) \int dz \int dz^* \exp(-i\tau z / r^\alpha)]^N \to \exp[-n \int dz \int dz^* \exp(-i\tau z / r^\alpha)]. \tag{40}
\]

Performing the spatial integration observe every \( \mathbf{r} \) can be matched by an equivalent \( -\mathbf{r} \) contribution, and assuming \( P^*(-z) = P^*(z) \) the integral becomes

\[
F(\tau) = \exp[-n2S_d \int_0^{\infty} r^{d-1} dr \int_0^{\infty} dz P^*(z)(1 - \cos \tau z / r^\alpha)], \tag{41}
\]

where \( S_d \) is the surface area of a unit sphere in \( d \) dimensions (i.e., \( S_2 = 2\pi \) and \( S_3 = 4\pi \) etc.). We also note that \( F(-\tau) = F(\tau) \) and that in consequence Eq. (40) is best integrated by introducing the new variable \( y = \tau ||z|| / r^\alpha \). Then we find

\[
F(\tau) = \exp[-S_d \pi \tau \int_0^{\infty} \int_0^{\infty} dy \int_0^{\infty} dz \exp(-y^2 / \beta y^{d/\alpha+1})], \tag{42}
\]

where \( \beta d/\alpha = 2 \int_0^{\infty} dz P^*(z) z^{d/\alpha} \).

Let us analyze Eq. (42). We note that if \( P^*(z) \) does not have a finite variance, then \( \langle z^{d/\alpha} \rangle \) diverges for \( \alpha < d/2 \), for example, for charge-charge interactions in a charged amorphous solid. Further, even if a finite variance does exist, we note that the integral \( \int_0^{\infty} dy \exp((1-cos y) y^{d/\alpha+1}) \) diverges for \( \alpha \leq d/2 \). \( \tag{43} \)
for both $d = 2$ and $d = 3$. If, on the other hand, it turns out that charged media do have $D(\omega) \sim \omega^4$, it is a strong indication that charge-charge interactions are not playing an important role in the reconstruction of their density of states.

Next use Eq. (42) to find the $P(f)$ in the case of elastic interactions. In this case, $\alpha = d$ and Eq. (42) becomes

$$F(\tau) = \exp \left[ -\frac{S_d n[|\tau|]}{d} \int_0^\infty dy \frac{(1 - \cos y)}{y^2} \right],$$

$$= \exp \left[ -\frac{\pi S_d n[|\tau|]}{2d} \right]. \quad (44)$$

Substituting $F(\tau) = \exp(-\delta f|\tau|)$ into Eq. (38), we find

$$P(f) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} d\tau e^{i(f-\delta f)|\tau|}$$

$$= \frac{1}{\pi} \int_0^\infty d\tau \cos f \tau \exp(-|\delta f|\tau) = \frac{1}{\pi} \frac{|\delta f|}{(\delta f)^2 + f^2}.$$ \hfill (45)

Thus we see we have a Lorentzian distribution with a mean $(f)$ and a standard deviation

$$\sigma_f = \delta f = \frac{\pi S_d n[|\tau|]}{2d}. \quad (46)$$

Now combining Eqs. (10), (31), (32), (33), and (34), we find

$$D(\omega) \approx C \int_0^\infty \omega_1 d\omega_1 \frac{(\delta f/\pi)}{f_0(\omega_1, \omega)^2 + \delta f^2} \frac{M^3 \omega_1^4}{3A f_0(\omega_1, \omega)}$$

$$\times \sqrt{\omega_1^2 + \frac{3A f_0(\omega_1, \omega)^2}{M^3 \omega_1^4}}$$

$$= C \int_0^\infty \omega_1 d\omega_1 \frac{(\delta f/\pi)}{f_0(\omega_1, \omega)^2 + \delta f^2} \frac{M^3 \omega_1^4}{3A}$$

$$\times \sqrt{\frac{\omega_1^2}{f_0(\omega_1, \omega)^2} + \frac{3A}{M^3 \omega_1^4}}. \quad (47)$$

Let us now introduce a new integration variable $t$ by $\omega_1 = \omega e^t$, then first from Eq. (37):

$$f_0(t, \omega) = \omega^3 \sqrt{(1 - t^2)(\frac{M^3 \omega^4}{3A})}, \quad (48)$$

and therefore

$$D(\omega) \approx \omega^4 C \int_0^1 dt \omega^6 (1 - t^2)(\frac{M^3 \omega^4}{3A}) + \delta f^2 \frac{M^3 \omega^4}{3A}$$

$$\times \sqrt{t^2/[1 - t^2)(\frac{M^3 \omega^4}{3A})] + \frac{3A}{M^3 \omega^4}}.$$ \hfill (49)

As $\omega \rightarrow 0$, this integral reduces to

$$D(\omega) \approx \frac{C\omega^4}{\pi \delta f} \int_0^1 t^5 dt \frac{M^3 \omega^4}{3A} \sqrt{t^2/[1 - t^2)(\frac{M^3 \omega^4}{3A})] + \frac{3A}{M^3 \omega^4}}.$$ \hfill (50)

Equation (50) yields the desired $D(\omega) \sim \omega^4$ behavior for the DOS.

In summary, the derivation of the universal density of states rests on one crucial assumption and one uncontrolled approximation, as explained above. To test the crucial approximation Eq. (37), we turn now to the GPS numerical model and examine it for different laws of interaction.

### IV. THE GPS MODEL AND NUMERICAL RESULTS

In this section, we explore further the model proposed by GPS [5]. This model considers $N$ anharmonic oscillators on a three-dimensional lattice. The $i$th oscillator is attached to the position $r_i$, and the total energy of the system is

$$U = \sum_i \left( \frac{1}{2} k_i x_i^2 + A x_i^4 \right) + \sum_{i \neq j} J_{ij} x_i x_j, \quad (51)$$

where $k_i$ are chosen randomly such as that in the notation of Sec. III A $g_0(\omega) \propto \omega^2$. Note that with this choice, one guarantees (in three dimensions) the convergence of the integral Eq. (20); see below for a counterexample. The coefficient of anharmonicity is chosen: $A = 1$. The interaction terms $J_{ij}$ are

$$J_{ij} \equiv J_0 \frac{b_{ij}}{r_{ij}^4}, \quad (52)$$

with $J_0 = 0.1$, $b_{ij}$ is chosen from a flat distribution $b_{ij} \in \{-0.5, 0.5\}$, and $\alpha$ controls the range of interaction. We will explore below the values $\alpha = 1, 2, 3$. The latter value $\alpha = 3$ is the one studied in Ref. [5], resulting in $\omega^4$ law at small frequencies.

Starting with the three-dimensional model with periodic boundary conditions, at each lattice site we put an oscillator with an initial displacement $x_i$ taken randomly from a uniform distribution $x_i \in [-0.005, 0.005]$. We use conjugate gradient minimization to obtain an equilibrated configuration where the many-body problem of determining $x_0$ is solved numerically. After computing the Hessian, the eigenvalues and frequencies of the modes are found. Repeating the procedure with many random realizations, the density of states is determined by straightforward binning.

As explained in Sec. III C after Eq. (36), it is quite impossible to determine analytically the distribution of forces $f_i$. But here we can do this easily, and in Fig. 5 we show the PDF of $f_i \equiv \sum_j J_{ij} x_{j0}$, \hfill (53)

as a function of system size. Here $N = 3375, 8000$, and 15 625. We expect from the analysis of Sec. III C that in dimension $d = 3$, the PDF of forces will converge nicely for $\alpha = 3$, will be marginal for $\alpha = 2$, and will not converge for $\alpha = 1$. This is precisely what we find, cf. Fig. 5. We note for $\alpha = 3$ not only that the PDF converges very well as a function of system size, it is very close in form to a Lorentzian PDF as is expected by the theory. In contrast, for $\alpha = 1$, not only does the PDF of the forces not converge as a function of the system size, it deviates more and more strongly from a Lorentzian form when the system size increases. It even develops a dip at $f = 0$, and if this dip continues to develop for larger systems (outside the scope of our numerics at this point in time), we would expect that the density of states with $\alpha = 1$ would not follow the universal law Eq. (1).

Contrary to this expectation, the direct measurement of the density of states does not show a major difference at the
FIG. 5. Probability distribution function of forces $P(f)$ for different system sizes, for the GPS model in three dimensions with $\alpha = 3$ (a), $\alpha = 2$ (b), and $\alpha = 1$ (c). In all cases, we employed 10,000 independent realizations. As expected from the analysis in Sec. III C, full convergence is observed in (a), marginal convergence in (b), and no convergence in (c).

low-frequency regime for the different values of $\alpha$. This can be seen in Fig. 6 where results are shown for the largest system size available (i.e., $N = 15625$) for the three values of $\alpha$. One cannot say that there is a very large difference between the resulting scaling laws. This is an indication that the actual form of a Lorentzian PDF that is employed in Sec. III C is not really needed, and it is sufficient, in fact, that $P(f = 0)$ is not zero. Whether or not for $\alpha = 1$ $P(f = 0) \rightarrow 0$ when $N \rightarrow \infty$ is a question that cannot be answered at present and has to remain for future analysis.

It is relevant, however, to comment that for $\alpha = 3$ we can observe in Fig. 6 the result of the first reconstruction. This is evidenced by the slope of about unity as indicated by the dashed line, which is in agreement with $g_1(\omega) \propto \omega$ at intermediate low frequencies. It is therefore interesting to destroy by hand the convergence of the integral in Eq. (20). We do it by choosing $g_0$ to be uniform in the interval $[0,1]$. We expect to lose the linear dependence of $g_1(\omega)$, with unknown consequences for the final form of $D(\omega)$. Indeed, in Fig. 7 we present the density of states for this choice of the GPS model with $\alpha = 3$. The result is quite surprising: the linear regime with a slope unity disappears, but the low frequencies of the density of states still conform (to as good an approximation as above) with Eq. (10). The lesson drawn from this and the other numerical results shown above is provided in Sec. V.

V. SUMMARY AND DISCUSSION

In summary, we first examined numerically the density of states of a model of charged granular solid and found that in the lowest frequency end it agrees with the universal law Eq. (1). Since this model contains long-range interactions, we returned to the theoretical considerations of Refs. [3–6] to clarify the expectations of how the density of states should depend on different laws of interactions. We reviewed this theory paying attention to the assumptions and approximation made. We found that the theory predicts a failure in the first reconstruction when $\alpha$ in Eq. (35) is too small. We also expect a failure in the second reconstruction in such a case, since
FIG. 7. The low-frequency regime of the density of states of the GPS model computed with a uniform distribution $g_0$ in the interval $[0,1]$. Here we employ 5000 realizations of a system with $N = 8000$. We see a loss of the linear regime $g_1 \propto \omega$, as expected, but we still get the universal behavior at low frequencies!

the PDF $P(f)$ is not expected to converge. Direct calculations using the GPS model verify that indeed $P(f)$ does not converge for $\alpha = 1$ and $d = 3$, and the linear reconstruction also disappears. And yet, the direct calculation of the density of states showed that Eq. (1) is extremely robust, oblivious of all these delicacies. This finding indicates strongly that further research to uncover the surprising robustness of this scaling law is still called for. It is not impossible that one reason for this robustness is that the model does not suffer from the approximation embodied in the transition from Eq. (36) to Eq. (37). The divergence that the theory predicts may result from this approximation. We hope that this paper will inspire future research to unravel further the interesting issues discussed here.

ACKNOWLEDGMENTS

We thank E. Bouchbinder for bringing the GPS model to our attention, including the role of the exponent $\alpha$. This work has been supported in part by the US-Israel Binational Foundation and by the cooperation project COMPAMP/DISORDER jointly funded by the Ministry of Foreign Affairs and International Cooperation (MAECI) of Italy and by the Ministry of Science and Technology (MOST) of Israel.
