**ABSTRACT**

Phage \(\lambda\) propagation in *Escherichia coli* host cells requires transcription antitermination on the \(\lambda\) chromosome mediated by \(\lambda\)N protein and four host Nus factors, NusA, B, E (ribosomal S10) and G. Interaction of *E. coli* NusB:NusE heterodimer with the single stranded *BoxA* motif of \(\lambda\)nutL or \(\lambda\)nutR RNA is crucial for this reaction. Similarly, binding of NusB:NusE to a *BoxA* motif is essential to suppress transcription termination in the ribosomal RNA (rrn) operons. We used fluorescence anisotropy to measure the binding properties of NusB and of NusB:NusE heterodimer to *BoxA*-containing RNAs differing in length and sequence. Our results demonstrate that *BoxA* is necessary and sufficient for binding. We also studied the gain-of-function D118N NusB mutant that allows \(\lambda\) growth in *nusA1* or *nusE71* mutants. *In vivo* \(\lambda\) burst-size determinations, CD thermal unfolding measurements and X-ray crystallography of this as well as various other NusB D118 mutants showed the importance of size and polarity of amino acid 118 for RNA binding and other interactions. Our work suggests that the affinity of the NusB:NusE complex to *BoxA* RNA is precisely tuned to maximize control of transcription termination.

**INTRODUCTION**

Phage \(\lambda\)-mediated antitermination in *Escherichia coli* enables RNA polymerase (RNAP) to read through early transcription termination sites on the phage chromosome (1). Antitermination is regulated *via* the direct interaction of N protein and the transcription elongation complex (TEC) formed by RNA, RNAP and the Nus (N utilization substance) host factors NusA, NusB, NusE (S10 ribosomal protein) and NusG (2–4). N-mediated antitermination is coupled to transcription of the phage \(\lambda\) nut RNA sites, each consisting of the single stranded *BoxA* and the palindromic stem–loop *BoxB* linked by a *spacer* sequence to which NusA binds (5). N interacts with *BoxB* and converts the TEC to a termination-resistant form (6,7). Binding of \(\lambda\) N to *BoxB* results in an indirect interaction with RNAP through NusA (8,9). NusB interacts with the *nut* site by binding to *BoxA*, an interaction that is ~10-fold strengthened upon NusE:NusB heterodimer formation (10–13). The NusB:NusE:RNA ternary complex is proposed to associate with RNAP through NusE (1,14,15). A similar complex in which \(\lambda\) N is replaced by phage HK022 Nun protein induces transcription arrest on the \(\lambda\) chromosome (7).

In addition to its involvement in transcription, NusE participates in translation as part of the 30S ribosomal subunit (16–18).

A termination-resistant TEC also assembles during transcription of *rrn* operons in *E. coli* and other bacteria (19,20). In addition to Nus factors, ribosomal proteins S4, S2, L4 and L13 participate in transcription regulation (21,22). *BoxA* is highly conserved in all seven *E. coli* *rrn* operons. A promoter-proximal *BoxB*-like element is present but is not required for *rrn* antitermination (23). As is the case with \(\lambda\) N, formation of the ternary NusB:NusE:*BoxA* complex is a key step during \(\lambda\) processive antitermination (13).

The structure of the NusB:NusE\(_{\text{Loop}}\) complex, in which the 22 residue ribosome-binding loop of NusE was deleted, has recently been determined (24). Analysis of this structure and other data (25) suggest that NusE is the active partner of the complex and that NusB mainly acts as a loading factor for NusE, a notion that is...
supported by the fact that NusE in a NusB deletion background could still support N antitermination and Nun termination (24). Although UV-crosslinking studies indicate that both NusB and NusE\textsuperscript{loop} contact BoxA RNA, detailed structural information about the RNA binding of NusB and the ternary NusB:NusE:RNA complex is not currently available.

Several nutR BoxA mutants abolish N-mediated antitermination or N-mediated transcription arrest in vivo and/or in vitro, namely nutR BoxA\textsubscript{5} (G35U) (26), nutR BoxA\textsubscript{16} (C38A) (27), nutR BoxA (U39G) (28). Oddly, the 9-bp transversion mutant nutR BoxA\textsubscript{69} has little effect on N-mediated antitermination except to make it NusB-independent, and it was proposed that NusB competed for BoxA binding with an as yet unidentified inhibitor of N activity (14).

NusB101 (D118N) presents an intriguing gain of function variant that suppresses a block in N-mediated antitermination or Nun-mediated transcription arrest (14, 15). Four Nus-factors, namely NusB, NusE, NusA, and NusG, have little effect on N-mediated antitermination except to make it NusB-independent, and it was proposed that NusB competed for BoxA binding with an as yet unidentified inhibitor of N activity (14).

In the present study, we used biophysical and genetic approaches to delineate identity elements of nut RNA that are recognized by NusB and by heterodimeric NusB:NusE complex. Furthermore, we studied NusB D118 mutants to clarify the role of this amino acid in NusB:RNA and NusB:NusE:RNA interactions.

**MATERIALS AND METHODS**

**Cloning, expression and protein purification of Nus-factors**

The musB gene was cloned via BamH1 and Nde1 restriction sites into the E. coli expression vector pET29b (Novagen, Madison, WI, USA). *Escherichia coli* strain BL21(DE3) (Novagen, Madison, WI, USA) harboring the recombinant plasmid was grown at 37°C in LB (Luria–Bertani) medium containing kanamycin (30 μg/ml) until an OD\textsubscript{600} = 0.5 was reached, then the temperature was reduced to 20°C for 30 min and the cells were induced by 1 mM IPTG. After induction overnight, the cells were harvested and resuspended in four times the pellet weight of lysis buffer (50 mM Tris, 150 mM NaCl, 1 mM DTT, pH 7.5). At this point, the NusB cell extract solved in the same buffer was added. After mixing for 20 min the cells were lysed with a micro-fluidizer (Microfluidics, Newton, MA, USA), and additional mixing was performed for 1 h to ensure correct formation of the NusB:NusE dimer. After centrifugation the dimer was purified from the supernatant via a GSTrap-FF column (GE Healthcare) using a one step elution (lysis buffer with 15 mM reduced glutathione). The GST-NusE fusion protein was cleaved by PreScission protease while dialyzing against lysis buffer at 4°C overnight. The cleaved protein was reapplied to a GSTrap-FF column using the same step elution procedure, but this time allowing the flow-through. For further purification the eluted fractions containing NusB:NusE were pooled and concentrated with Vivasin concentrators (Vivascience, MWCO 5000 Da). The concentrated sample was applied to an S75 gel filtration column (GE Healthcare). The fractions containing NusB were pooled and dialyzed against buffer as used for fluorescence measurements (25 mM HEPES, 100 mM potassium acetate, pH 7.5). The identity and structural integrity of the purified protein was analyzed by 19% SDS–PAGE and NMR spectroscopy.

**NusB mutations**

For NusB\textsuperscript{D118N} (NusB101), NusB\textsuperscript{D118R}, NusB\textsuperscript{D118A}, NusB\textsuperscript{D118E} and NusB\textsuperscript{D118K} the mutation primers shown in Supplementary Table S1 were used. Mutations were introduced by using the QuikChange protocol (Stratagene, La Jolla, CA, USA). Expression and purification was as described for wildtype NusB. NusB\textsuperscript{K2E} was inherent in the original NusB pETM11-plasmid (24).

**NusE:NusB complex**

NusE was cloned via BamH1 and EcoR1 restriction sites into the E. coli expression vector pGEX-6P (GE Healthcare) (24). The recombinant plasmid encoded a GST-NusE fusion protein with an internal PreScission cleavage site following the GST-tag. *Escherichia coli* strain BL21(DE3) (Novagen) harboring the recombinant plasmid was grown at 37°C in LB medium containing ampicillin (100 μg/ml) until an OD\textsubscript{600} = 0.5 was reached, then the temperature was reduced to 20°C for 30 min and the cells were induced by 1 mM IPTG. After induction overnight, the GST-NusE fusion protein was cleaved by PreScission protease while dialyzing against lysis buffer at 4°C overnight. The cleaved protein was reapplied to a GSTrap-FF column using the same step elution procedure, but this time allowing the flow-through. For further purification the eluted fractions containing NusB:NusE were pooled and concentrated with Vivasin concentrators (Vivascience, MWCO 5000 Da). The concentrated sample was applied to an S75 gel filtration column (GE Healthcare). The fractions containing NusB were pooled and dialyzed against buffer as used for fluorescence measurements (25 mM HEPES, 100 mM potassium acetate, pH 7.5). The identity and structural integrity of the purified protein complexes were analyzed by 19% SDS–PAGE.

**NusB\textsuperscript{D118E}–NusE\textsuperscript{loop} production and purification for crystallization**

Cloning of the genes encoding NusB and NusE\textsuperscript{loop} has been described (24). Mutations were introduced by using the QuikChange protocol (Stratagene, La Jolla, CA, USA). To produce protein for crystallographic analysis, plasmids containing the genes of interest were...
co-transformed into *E. coli* strain BL21(DE3) by electroporation. The cells were grown in auto-inducing medium (31) in the presence of the appropriate antibiotics to an OD<sub>600</sub> of 0.5 at 37°C, and then incubated for an additional 16 h at 20°C. After harvesting at 4°C, the cell pellets were washed with binding buffer (50 mM Tris, pH 7.5, 150 mM NaCl) and stored at −80°C. Purification of the NusB<sup>DD18N</sup>;NusE<sup>Δloop</sup> complex followed a double affinity chromatography procedure as described for the NusB:NusE<sup>Δloop</sup> complex (24).

**Crystallographic analysis**

NusB<sup>DD18N</sup>;NusE<sup>Δloop</sup> complex (NusB101;NusE<sup>Δloop</sup>, 16 mg/ml) was crystallized at 20°C *via* the sitting drop vapor diffusion method by mixing 1 ml of sample with 1 ml of reservoir solution (0.2 M potassium citrate, 20% PEG 3350). Crystals could be flash frozen in liquid nitrogen after transfer into 60% reservoir plus 40% glycerol. Diffraction data were collected at 100 K on beamline PXII (SLS, Villigen, Switzerland) using a MarCCD 225 mm detector. The data were processed with the XDS package (32).

The structure of the NusB<sup>DD18N</sup>;NusE<sup>Δloop</sup> complex was solved by molecular replacement using the coordinates of the NusB:NusE<sup>Δloop</sup> complex [PDB ID 3D3B; (24)]. The model was manually rebuilt using COOT (33) and refined by standard methodology using Refmac5 including TLS refinement (34). Each protein molecule in the crystallographic asymmetric unit represented a separate TLS group.

**In vivo assays**

*nusB::Cam nusA<sup>+</sup>* or *nusB::Cam nusA<sup>1</sup>* mutants carrying λ<sup>cI857</sup> prophage were constructed. Wild-type and mutant NusB were supplied from a pBAD30 plasmid. Phage burst size after thermal induction was determined according to standard protocols.

**Fluorescence equilibrium measurements**

Various RNA sequences corresponding to the *nut* regions of the λ genome or to the *rrnG Box A* of the *E. coli* genome (Supplementary Table S2) were used. Fluorescence equilibrium titrations were performed using an L-format Jobin–Yvon Horiba Fluoromax fluorimeter (Edison, NJ, USA). Extrinsic fluorescence measurements with 3′-6-carboxy-fluorescein (6-FAM)-labeled RNA were performed in fluorescence buffer as above in a total volume of 1 ml using a 10 × 4 mm quartz cuvette (Hellma, Müllheim, Germany). The excitation wavelength was 492 nm, and the emission intensity was measured at 516 nm applying a 500 nm cutoff filter. Anisotropic measurements were performed with slit widths of 4 nm and 3 nm for excitation and emission, respectively. All titration measurements were carried out at 25°C with 50 nM of 6-FAM-labeled RNA. Following sample equilibration, six data points with an integration time of 0.8 s were collected for each titration point.

### Data fitting

Anisotropic data were fitted to a two-state binding model to determine the equilibrium dissociation constant (*K<sub>d</sub>*<sup>+</sup>)<sup>−</sup> using standard software. The anisotropy was calculated from:

\[
A = f_{\text{complex}} \cdot A_{\text{complex}} + f_{\text{RNA}} \cdot A_{\text{RNA}}
\]

where *A*, *A<sub>complex</sub>*<sup>−</sup> and *A<sub>RNA</sub>*<sup>−</sup> are anisotropies and *f<sub>complex</sub>*<sup>−</sup> and *f<sub>RNA</sub>*<sup>−</sup> are fractional intensities. The change in fluorescence intensity has to be taken into account, so that the bound fraction is given by

\[
\frac{[\text{complex}]}{[\text{RNA}]_0} = \frac{(A - A_{\text{RNA}})}{(K_d + [P]_0 + [\text{RNA}]_0)}
\]

\[
A = \frac{(A - A_{\text{RNA}})}{([P]_0 + [\text{RNA}]_0) + (R \cdot (A_{\text{complex}} - A))} + \frac{\sqrt{(K_d + [P]_0 + [\text{RNA}]_0)^2 - 4[P]_0[\text{RNA}]_0}}{2[\text{RNA}]_0}
\]

CD measurements

Far UV CD measurements were performed on a J-810 S spectropolarimeter with a CDF-426S temperature control unit (JASCO International, Tokyo, Japan). Samples were prepared by dialyzing protein solutions against 10 mM sodium phosphate buffer, pH 7.5. Spectra were recorded at 25°C in a wavelength range of 185–260 nm with 50 nm/min scanning speed in a 1 mm path length quartz cuvette (Hellma, Müllheim, Germany) at a protein concentration of 10 μM. Buffer spectra were subtracted and ten spectra were accumulated. In order to normalize the measured ellipticity the mean residue molar ellipticity was calculated as:

\[
[\Theta]_{MRW} = \frac{\Theta}{(c \cdot d \cdot N)}
\]

*Θ*, measured ellipticity; *MRW*, mean residue mass; *c*, protein concentration; *d*, path length; *N*, number of amino acids.

Thermal stability was analyzed by monitoring the CD signal at 222 nm during heating from 25°C to 90°C with a heating rate of 1°C/min. Quartz cuvettes with 1 cm path length equipped with a stirrer were used at a protein concentration of 2.5 μM. Both baselines and the transition region were fitted simultaneously:

\[
y_{\text{obs}} = \frac{(y_n + m_n \cdot T_m)}{(1 + \exp(\Delta H_m/R \cdot (1/T_m - 1/T)))} + \frac{(y_d + m_d \cdot T \cdot \exp(\Delta H_m/R \cdot (1/T_m - 1/T)))}{(1 + \exp(\Delta H_m/R \cdot (1/T_m - 1/T)))}
\]

*Y<sub>obs</sub>*: observed ellipticity; *y<sub>n</sub>, y<sub>d</sub>* y-intercepts of the baselines of native and denatured protein; *m<sub>n</sub>, m<sub>d</sub>* baseline slopes.
\( \Delta H_m \) is the enthalpy at the temperature of the melting point \( (T_m) \) (35,36). Evaluations were based on the assumption that the unfolding transition is a two-state reaction. The temperature dependence of \( \Delta G_D \) (free energy of unfolding) can be predicted at any temperature from the modified Gibbs–Helmholtz equation:

\[
\Delta G_D(T) = \Delta H_m(1 - T/T_m) - \Delta C_P(T_m - T + T \cdot \ln(T/T_m))
\]

Over the narrow temperature range of the transition effects of \( \Delta C_P \) (change in heat capacity) are negligible. Therefore, the equilibrium constant of the unfolding, \( K \), is defined as

\[
-K = \exp \left( \frac{\Delta H_m}{RT} + \frac{\Delta S_m}{R} \right)
\]

where \( T \) is the temperature in Kelvin, \( R \) is the gas constant and \( \Delta S_m \) is the entropy of unfolding at the melting point \( (T_m) \). When observing a two-state process with an experimental observable, \( y_{\text{obs}} \), the equilibrium constant for the reaction is

\[
K = \frac{(y_{\text{obs}} - \langle y_n \rangle)}{(\langle y_d \rangle + m_d \cdot T - y_{\text{obs}})}
\]

By combining equations 7 and 9, \( \Delta G_D \) can be calculated (36,37).

**RESULTS**

Fluorescence anisotropy measurements were performed to determine the dissociation constants of NusB or NusB:NusE and various RNA constructs (Tables 1 and 2).

**Formation of the dimeric NusB:NusE complex enhances RNA binding affinity**

NusB bound \( \text{rrnG } \text{BoxA-spacer} \) and \( \text{rrnG } \text{BoxA} \) with nearly identical efficiencies (dissociation constants \( K_d \) of 130 ± 20 nM and 200 ± 10 nM, respectively; Figure 1A, Table 1). The efficiency of NusB binding to \( \lambda \text{ nutR} \) BoxA-spacer, nutL BoxA-spacer and nutR BoxA sequences was significantly lower (\( K_d \) values of ~1.5 μM; Figure 1B). The higher anisotropy of \( \text{nutR BoxA} \) relative to the other constructs reflects the different rotational correlation time relative to the large RNA constructs. Preformed NusB:NusE heterodimer bound to all RNAs tested with affinities more than an order of magnitude greater than NusB alone, consistent with the findings that both NusB and NusE in the NusB:NusE complex make RNA contacts (24). \( K_d \) values for the \( \text{rrnG } \text{BoxA-spacer} \) and the \( \text{rrnG } \text{BoxA} \) were 8 ± 2 and 5 ± 1 nM, respectively (Figure 1A; Table 2), and 90 ± 37 nM for \( \text{nutR } \text{BoxA-spacer} \), 80 ± 22 nM for \( \text{nutL } \text{BoxA-spacer} \), and 83 ± 8 nM for \( \text{nutR } \text{BoxA} \) (Figure 1C; Table 2). These data also indicate that contacts of NusE to the spacer region previously seen by UV-induced crosslinking (24) do not significantly increase the RNA affinity of the complex.

**Protein RNA interaction takes place predominantly via BoxA**

The binding of NusB and NusB:NusE to \( \lambda \text{ nut BoxA-spacer} \) and \( \text{nutR BoxA} \) sequences with virtually identical affinities suggests that the spacer regions, shown previously to bind NusA (5), do not bind NusB or NusB:NusE. To confirm this, we measured binding to spacer alone. Specific binding of NusB or NusB:NusE to \( \text{nutL } \text{spacer} \) and \( \text{nutR } \text{spacer} \) was not observable in fluorescence titrations (Figure 1D). A slight increase of the fluorescence anisotropy signal with the NusB:NusE \( \text{nutR } \text{spacer} \) titration is consistent with unspecific binding with a \( K_d \)-value in the upper micromolar range.

**BoxA mutations decrease binding affinity**

Several \( \text{BoxA} \) mutations (Supplementary Table S2) affect \( \lambda \text{ N} \) antitermination and HK022 Nun transcription arrest (14,26–28). We studied the effect of these mutations on NusB and NusB:NusE binding affinities. No interaction with the \( \text{boxA} \) transversion mutant \( \text{nutR } \text{BoxA69-spacer} \) and either NusB or NusB:E heterodimer was detected (Figure 2A and B; Tables 1 and 2), clearly indicating that the binding of these factors is \( \text{BoxA} \) RNA

### Table 1. Dissociation constants for NusB monomer variants in nano molar

25 mM HEPES, 100 mM potassium acetate, pH 7.5.

nb = no binding detectable; empty cell = not determined. At least two independent experiments were performed per \( K_d \). The relative molecular weights of the amino acids at residue 118 are \( A < N < D < E < K < R \).
sequence-dependent. This result supports the in vivo finding of Patterson et al. (14) that N antitermination on BoxA69 fusions is NusB-independent. We next tested BoxA point mutants that inhibit N and Nun (Figure 2A and B; Tables 1 and 2). The nutR BoxA5 mutation (G35U) reduced NusB binding 2- to 3-fold ($K_d = 3.1 \pm 1.6 \mu M$). Interestingly, the affinity of NusB:NusE heterodimer for the mutant RNA was essentially identical to that of NusB ($K_d = 5.2 \pm 1.3 \mu M$). NusB and NusB:NusE bound nutR BoxA16 (C38A) with $K_d$ values of $5.1 \pm 1.4 \mu M$ and $3.4 \pm 1.8 \mu M$, respectively. The dissociation constants of NusB and NusB:NusE for nutR BoxA (U39G), which inhibits N, were $1.6 \pm 0.8 \mu M$ and $1.9 \pm 0.7 \mu M$, respectively. Judged from their effects on the NusB and NusB:NusE binding affinities, G35 and C38 participate more tightly in protein binding than U39. The equivalent

25 mM HEPES, 100 mM potassium acetate, pH 7.5. nb = no binding detectable; empty cell = not determined. At least two independent experiments were performed per $K_d$. The relative molecular weights of the amino acids at residue 118 are A < N < D < E < K < R.

Figure 1. Fluorescence anisotropy titration of fluorescein labeled λ nut and rrnG RNAs with NusB (open markers) and NusB:NusE complex (filled markers). (A) A 50 nM rrnG BoxA-spacer (squares) and 50 nM rrnG BoxA (circles) titrated with NusB and NusB:NusE. (B) Fifty nanomolar nutR BoxA-spacer (circles), nutL BoxA-spacer (squares) and nutR BoxA (triangles) titrated with NusB. (C) A 50 nM nutR BoxA-spacer (circles), nutL BoxA-spacer (squares) and nutR BoxA (triangles) titrated with NusB:NusE. (D) A 50 nM nutR spacer (circles) and 50 nM nutL spacer (squares) titrated with NusB and NusB:NusE. Solid lines represent the best fit to equation (3).
binding affinities of NusB and NusB:NusE heterodimer to these BoxA point mutants stands in sharp contrast to the enhanced binding of the heterodimer to wild-type BoxA sequences.

The NusB_{D118N} (NusB101) mutation affects RNA binding affinity

NusB_{D118N} is a gain-of-function mutation that enables NusB to override mutations in NusE and NusA that abrogate λ N-mediated antitermination (29,30). The dissociation constants for NusB_{D118N} complexes with rrnG BoxA-spacer and rrnG BoxA were 5- to 6-fold lower compared to wild-type NusB (Figure 3A; Table 3). Only small reductions in $K_d$ were observed for the nutL BoxA-spacer and nutR BoxA-spacer complexes, whereas the dissociation constant for the complex of NusB_{D118N} with nutR BoxA decreased significantly from ~1600 nM to ~290 nM (Figure 3B; Table 1). In contrast, the mutation increased the $K_d$ values about 3-fold for heterodimer complexes with rrnG BoxA-spacer and rrnG BoxA (Figure 3C, Table 2). NusB_{D118N}:NusE complexes with nutR BoxA-spacer and nutL BoxA-spacer sequences displayed 3- and 5-fold, respectively, lower $K_d$ values for the mutant relative to the wild-type heterodimer (Figure 3D, Table 3). For the NusB_{D118N}:NusE complex with nutR BoxA, the $K_d$ decreased by nearly an order of magnitude to $9 \pm 1$ nM (Figure 3D; Table 2). Thus, NusE did not further enhance the binding of NusB_{D118N} to rrnG BoxA or rrnG BoxA-spacer. However, NusE strongly stimulated the binding of NusB_{D118N} to sequences derived from nutL and nutR.

The structure of NusB_{D118N}:NusE_{Δloop} closely resembles the structure of NusB:NusE_{Δloop}

NusE_{Δloop} is a derivative of NusE that binds NusB and retains transcriptional but not translational activity (24). The NusB:NusE_{Δloop} complex binds RNA that includes a BoxA sequence, although with lower efficiency than NusB:NusE [(24); Figure S1; Table 2]. Previous studies demonstrated that NusB_{D118N}:NusE_{Δloop} bound RNA more tightly than NusB:NusE_{Δloop}. To ask if the increased RNA affinity of the NusB_{D118N}:NusE_{Δloop} complex correlated with structural rearrangements compared to the NusB:NusE_{Δloop} complex, we solved the crystal structure of the NusB_{D118N}:NusE_{Δloop} complex by molecular replacement at 2.5 Å resolution (Figure 4). The structure was refined to $R_{work}$ and $R_{free}$ factors of 20.4% and 25.6%, respectively (Table 4). An asymmetric unit of the crystal contained three molecules each of NusB_{D118N} and NusE_{Δloop}, which formed three NusB_{D118N}:NusE_{Δloop} complexes. Two of these complexes exhibited well-defined electron density, but the electron density map of the third complex was fragmentary: In that complex, residues 60–77 and 127–139 of NusB_{D118N} and residues 45–47 and 60–72 of NusE_{Δloop} could not be unambiguously traced. The following discussion therefore refers to the structures of the two well defined complexes, which closely resemble each other [RMSD of 0.75 Å for 220 Cα atoms; calculated with SSM (38)].

The global structure of NusB_{D118N} in complex with NusE_{Δloop} is very similar to that of wild-type NusB in isolation [PDB ID 1EY1; (39); rmsd of 2.54 Å for 110 Cα atoms; Figure 4]. Furthermore, the structure of the NusB_{D118N}:NusE_{Δloop} complex is virtually identical to that of the NusB:NusE_{Δloop} complex (RMSD of 0.85 Å for 220 Cα atoms; Figure 4B), demonstrating that the D118N mutation has no global conformational consequences. In particular, the positions and conformations of NusB residue N118 in the mutant and of residue D118 in the parent complex are essentially identical. Irrespective of the amino acid at position 118, the neighboring region undergoes identical adjustments upon NusE_{Δloop} binding, during which the Cz position of residue 118 is repositioned by 2.8 Å (Figure 4C, inset). However, the D118N exchange induces a significant difference in the local electrostatic surface properties of the complex (Figure 4D). This observation is consistent with the idea that the increased RNA affinity of NusB_{D118N} or its complex with NusE_{Δloop} is at least in part due to the replacement of a negatively charged residue with an uncharged residue at the RNA binding site, thus reducing repulsion with the negatively charged...
sugar-phosphate backbone of the RNA. Alternatively, or in addition, introduction of an asparagine for an aspartate at position 118 may result in additional hydrogen bonds to the RNA.

The overall structures of various NusB118 mutants are highly similar

To investigate further the effect of amino acid variations at position 118, several point mutations with positively charged, negatively charged, and apolar amino acids were examined. All NusB variants show CD-spectra typical of α-helices, i.e. minima at 208 nm and 222 nm as well as a maximum at 190 nm (Figure 5A), with only minor differences from the wild-type protein spectrum. The melting temperatures of NusB and NusB D118 variants were determined by thermal unfolding. The CD signal at 222 nm, which we used to indicate melting, was reduced by all mutations, particularly by substitutions with positively charged residues. The Gibbs free energy of the unfolded species \((\Delta G_D)\) at 328 K thus ranges from 8.3 ± 0.2 kJ/mol for wild-type NusB to 1.6 ± 0.2 kJ/mol for NusB D118K.

| Mutant   | \(T_M\) (K) | \(\Delta H_M [T_M]\) (kJ/mol) | \(\Delta G_D [328K]\) (kJ/mol) |
|----------|-------------|-------------------------------|-------------------------------|
| NusB     | 337.8 ± 0.1 | 280 ± 4                       | 8.3 ± 0.2                     |
| NusB\(^{D118N}\) | 333.6 ± 0.1 | 174 ± 3                       | 2.7 ± 0.2                     |
| NusB\(^{D118A}\) | 333.5 ± 0.1 | 340 ± 4                       | 5.6 ± 0.2                     |

Table 3. Melting temperatures \((T_M)\), free reaction enthalpy at the melting point \((\Delta H_M[T_M])\) and Gibbs free energy of the unfolding reaction at 328K \((\Delta G_D)\) values for NusB variants (10 mM potassium phosphate, pH 7.5)

sugar-phosphate backbone of the RNA. Alternatively, or in addition, introduction of an asparagine for an aspartate at position 118 may result in additional hydrogen bonds to the RNA.

Effects of other NusB D118 mutations on RNA binding

The binding properties of different NusB mutants dependent on the RNA were tested. Thus the binding of NusB\(^{D118K}\) to \(rrnG\) BoxA-spacer was approximately as tight as NusB\(^{+}\), whereas the affinity of the mutant for \(rrnG\) BoxA was 20% that of NusB\(^{+}\) (Figure 6; Table 1). NusB\(^{D118E}\) bound \(rrnG\) BoxA with wild-type efficiency but

NusB<sup>D118K</sup>, reflecting, perhaps, the larger volume of the former substitution. Of the various D118 substitutions, interaction with the nut<sub>R</sub> BoxA-spacer could be detected only for NusB<sup>D118N</sup> and NusB<sup>D118E</sup> (Figure 6 and Table 3). NusB<sup>D118E</sup> bound nut<sub>R</sub> BoxA as well as NusB<sup>+</sup>. NusB<sup>D118K</sup> and NusB<sup>D118R</sup> bound nut<sub>R</sub> BoxA significantly better than wild-type NusB (Figure 6 and Tables 1 and 2).

**NusE improves binding of NusB mutants**

With the exception of NusB<sup>D118E</sup>, NusE significantly enhanced mutant NusB binding to rrn<sub>G</sub> RNA, although no mutant except NusB<sup>D118N</sup> bound as well as NusB<sup>+</sup>. NusE, NusE also enhanced binding to nut<sub>R</sub> sequences. Binding of NusB mutants to nut<sub>R</sub> BoxA was, except for NusB<sup>D118E</sup>, at least as strong as NusB<sup>+</sup>. Thus, NusE may foster additional RNA contacts, rendering NusB-mediated interactions less dominant (Figure 7 and Tables 1 and 2).

NusB<sup>D118N</sup>, NusB<sup>D118K</sup> and NusB<sup>D118R</sup> suppress the nut<sub>A</sub><sup>Δ<sub>183R</sub></sup> mutation in vivo

We next tested the NusB D118 mutants for suppression of nut<sub>A</sub><sup>Δ<sub>183R</sub></sup>. NusB<sup>D118R</sup> prevents phage λ growth at 42°C by blocking λ N antitermination. Over-expression of NusB D118 mutants in a nut<sub>A</sub><sup>Δ<sub>183R</sub></sup> λ cl857 lysogen had modest negative effects on phage burst size (Table 5). The negatively charged NusB<sup>D118E</sup> was most inhibitory, reducing burst size to 32% of wild-type levels. In the nut<sub>A</sub><sup>Δ<sub>183R</sub></sup> background, all mutants except NusB<sup>D118E</sup> increased burst size >100-fold. NusB<sup>D118N</sup> suppressed nut<sub>A</sub><sup>Δ<sub>183R</sub></sup> with greatest efficiency, increasing burst size from <0.01% to 4.9% relative to nut<sub>A</sub><sup>+</sup>. NusB<sup>D118K</sup> and NusB<sup>D118R</sup> also significantly enhanced λ growth (2.2% and 3.3%, respectively, of nut<sub>A</sub><sup>+</sup> titers). Suppression by NusB<sup>D118N</sup> was the least effective (0.5%). Taken together, these data suggest that replacing the negatively charged asp118 with an uncharged asparagine residue or a positively charged lysine or arginine residue significantly restores λ N activity in a nut<sub>A</sub><sup>Δ<sub>183R</sub></sup> strain. Poor suppression by the alanine substitution may reflect the lower molecular weight of this aminoacid relative to aspartate. Similarly, the inability of NusB<sup>D118E</sup> to restore λ growth may also be caused by steric effects due to the bulky glutamate side chain, in spite of its negative charge.

**DISCUSSION**

Processive transcription antitermination depends on formation of a multi-factorial ribonucleoprotein complex on the surface of RNAP in response to nut<sub>R</sub> signaling sequences in the untranslated leader regions of transcripts. These factors include NusA, NusB, NusE and NusG (2–4). In the case of λ Δ<sub>mut</sub>, λ N protein forms part of the complex, whereas the complex that forms at rrn nut<sub>R</sub> includes the Nus proteins and a number of additional host factors (21,22). Protein–protein and protein–RNA interactions in these complexes are cooperative in the sense that a stable complex is assembled based on numerous, but often weak, binary interactions. While some
of these binary interactions have been mapped within the complexes, little is known about their relative strengths and how important these are for generating functional complexes. Here, we have used a combination of biophysical and functional studies to explore interactions between NusB or NusB:NusE complex and the nut BoxA RNA signaling sequence to which it binds.

We confirm that the affinity of NusB:NusE for BoxA is an order of magnitude higher than that of NusB alone (13), reflecting, presumably, the additional contacts that NusE makes with BoxA. We find that mutations in λ nut BoxA that inhibit λ N antitermination reduce NusB binding. However, in contrast to λ nut BoxA+, the affinities of NusB and NusB:NusE for the mutant BoxA sequences are essentially identical. The mutations lie throughout BoxA and do not define the known sites of NusE–RNA interactions (24).

The $K_d$ values reported above for the association of NusB or NusB:NusE with λ nut BoxA are similar to those reported by Greive and coworkers based on fluorescence anisotropy experiments (13). We note, however, a large difference with respect to rrnG BoxA-spacer binding. These authors report a $K_d$ of 850 nM for NusB and 200 nM for NusB:NusE, whereas we observe values of 130 nM and 8 nM, respectively. Since the RNA sequences tested were identical, we suggest that the lower affinity seen by Greive et al. reflects the 5' location of the fluorescent label on their RNA compared to the 3' location used in our experiments. The N-terminus of NusB contacts both rrn BoxA and nut BoxA at their 5'-ends, and interference with these contacts by a 5' label could increase the $K_d$ values, although in an RNA sequence-dependent manner. Indeed, we find that the K2E mutation increased the $K_d$ of the NusB rrn BoxA-spacer complex from 130 nM to 3600 nM, but raised the $K_d$ of NusB binding to nutL BoxA-spacer only 2-fold (from 2200 nM to 5100 nM).

Fluorescence anisotropy measurements with fluorescein labeled $\lambda$nut and rrrG RNAs to NusB$^{D118A}$, NusE (open circle, fit: solid line), NusB$^{D118R}$-NusE (filled square, fit: dashed line), NusB$^{D118E}$-NusE (open triangle, fit: pointed line) and NusB$^{D118K}$-NusE (filled triangle, fit: dashed/pointed line). Lines represent the best fit to equation (3). (A) Fifty nanomolar rrrG BoxA; (B) 50 nM rrrG BoxA-spacer; (C) 50 nM nutR BoxA; and (D) 50 nM nutR BoxA-spacer.
We have also explored the phenotype of the NusB\textsuperscript{D118N} (NusB101) mutation. NusB\textsuperscript{D118N} suppresses mutations in NusA and NusE that inhibit \( \lambda \) N antitermination function (29,30). It has been proposed that an increase in the affinity of NusB\textsuperscript{D118N} for nut RNA compared to NusB\textsuperscript{+} may compensate for weaker RNA (or protein) contacts of the mutant Nus proteins (24, 29). We show here that the D118N mutation enhances NusB binding to both \textit{rrn BoxA} and \( \lambda \) nut \textit{BoxA}. The mutation reduces binding to \( \lambda \) nut \textit{BoxA} mutants, \textit{BoxA5} and \textit{BoxA9(U39G)}, but has no effect on binding to \textit{BoxA16}. It will be interesting to test whether the D118N mutation further reduces \( \lambda \) N antitermination on \textit{BoxA} mutant templates in \textit{vivo}. D118N also enhances NusB binding to \textit{nut BoxA} in complex with NusE. However, we find that the affinity of NusB\textsuperscript{D118N}:NusE for \textit{rrn BoxA} is only 20\% that of NusB\textsuperscript{+}:NusE. These data imply that D118N, although it optimizes the formation of the \( \lambda \) N antermination complex, interferes with the assembly of antitermination complexes on \textit{rrn} operons.

The enhanced affinity of NusB\textsuperscript{D118N} to \textit{BoxA} is not due to gross distortions in the shape of the NusE complex. Thus, the structure of NusB\textsuperscript{D118N},NusE\textsuperscript{\textit{A}\textsubscript{loop}} complex is virtually identical to NusB\textsuperscript{+}:NusE\textsuperscript{\textit{A}\textsubscript{loop}}, although the electrostatic surface properties are strongly affected (Figure 4D). In fact, CD spectroscopic analyses (Figure 5) show that NusB also structurally tolerates a number of other mutations at position 118. Thus, the effects of the D118 mutations on RNA binding are local.

D118 is located close to NusB residues that interact with \textit{BoxA} RNA. It was suggested that removal of the negatively charged aspartate with the neutral asparagine residue might extend the NusB RNA-binding surface and that this might stabilize the antitermination complex and account for the suppression of \textit{nut} \textit{BoxA} and \textit{nusE71}. Our results in general support this notion, although we find that the size of the D118 substitution also plays a role in the affinity of NusB for RNA.

The differential RNA affinities of the mutant NusB:NusE complexes roughly correlate with their \textit{in vivo} suppression activity. We measured the burst sizes after induction of a \( \lambda \) c1857 lysogen in NusB\textsuperscript{+} and \textit{nusA1} hosts. This assay, which reflects the ability of \( \lambda \) N to antiterminate, showed that the order of \textit{nusA1} suppression efficiency was D118N > D118R > D118K > D118A. D118E failed to increase \( \lambda \) burst size over that seen for NusB\textsuperscript{+}. The binding affinities to \textit{nut BoxA} for the mutants in complex with NusE was D118N > D118R > D118K > D118A > D118E. Note that the \( K_d \) of NusB\textsuperscript{+} for \textit{nut BoxA} (83 nM) was not significantly different from that of NusB\textsuperscript{D118K} (75 nM), yet the mutant NusB increased the \( \lambda \) burst size in a \textit{nusA1} host at least 100-fold above the wild-type NusB level. This disjunction between RNA binding and \( \lambda \) activation is, as yet, unexplained. It implies, however, that D118 may make functionally important contacts within NusB or with NusE.

We propose that D118 does not contact \textit{BoxA}, but that removal of the negative charge permits such interaction. The location of position 118 opposite the NusB:NusE interaction surface renders an effect of mutations at this position on the NusB:NusE interaction unlikely. However, it cannot be ruled out completely, and a more definitive verdict needs further structural analysis of the NusB:NusE:\textit{BoxA} complex. Study of how NusB mutations affect complex formation with NusE\textsuperscript{\textit{A}\textsubscript{loop}} and alter its RNA binding properties might shed further light on the role of the NusE loop in RNA binding.

The results from our combined biophysical and genetic investigations illustrate how a particular protein–RNA interaction is fine-tuned with respect to other interactions within a functional ribonucleoprotein complex to achieve processive transcriptional antitermination. Furthermore, our results refine the mechanism by which NusB acts as a NusE RNA loading factor (24). NusB:NusE:RNA complex formation is entirely mediated by the \textit{BoxA} sequences, whereas the \textit{spacer} regions are necessary and sufficient for NusA binding (5). Sterically, simultaneous binding of these Nus factors to \textit{nut} and \textit{rrn} should be possible. There is, however, no evidence that NusA and NusB:NusE interact at \textit{nut}, and no increase in \textit{nut} binding by NusB:NusE was observed on NusA addition (15).
