Abstract: This paper presents a comprehensive theoretical study of the magnetic-tunable near-field radiative heat transfer (NFRHT) between two twisted graphene gratings. As a result of the quantum Hall regime of magneto-optical graphene and the grating effect, three types of graphene surface plasmon polaritons (SPPs) modes are observed in the system: near-zero modes, high-frequency hyperbolic modes, and elliptic modes. The elliptic SPPs modes, which are caused by the combined effect of magnetic field and grating, are observed in the graphene system for the first time. In addition, the near-zero modes can be greatly enhanced by both grating and magnetic field, rendering graphene devices promising for thermal communication at ultra-low frequency. The combined effect of grating, magnetic field, and twist is investigated simultaneously. The external magnetic field improves the abilities of graphene filling factor and twisted angle to modulate NFRHT. In particular, the magnetic field endows the twist action with a higher modulation range of heat transfer, especially for large graphene filling factors when elliptic and hyperbolic modes exist. In sum, the combined effect of magnetic field and twist provides a tunable way to realize the energy modulation or multi-frequency thermal communications related to graphene devices.
I. INTRODUCTION

Near-field radiative heat transfer (NFRHT), first proposed by Rytov [1] and formalized by Polder and Van Hove [2], can exceed Planck’s blackbody limit by several orders of magnitude in nanoscale separation distance. In recent years, rapid progress has been achieved in nanoscale thermal radiation [3-14]. Graphene, a monolayer sheet of carbon atoms, exhibits intriguing electronic properties that arise from its massless Dirac dispersion of electrons. Owing to its unusual physical characteristics, graphene is a promising candidate for fundamental research and new applications [15-17].

Graphene surface plasmon polaritons (SPPs) can be excited in the near-field regime to transport energy in photonic channels [18]. In recent years, several theoretic studies on NFRHT concerning graphene have emerged. The near-field radiative heat transfer has been investigated between two suspended graphene sheets [19, 20], two graphene sheets patterned in ribbon arrays [21], graphene disks [22-25] and multilayer graphene systems [26-32]. Given its excellent modulating performance and strongly confined SPPs, graphene can greatly enhance and tune NFRHT when it is coated on dielectric materials [33-35] either in parallel-plate configurations [18, 26, 36-41] or grating geometry [42-47]. Moreover, graphene can enhance NFRHT for materials with nonmatching surface excitations [48]. Covering the cell of the near-field thermophotovoltaic system with a graphene monolayer enhances performance of the device [27, 36, 49-51]. However, existing research on modulating NFRHT with graphene is based on tuning the chemical potential of graphene by electronic method or doping.

In consideration of the magneto-optical characteristics of semiconductors, such as InSb, an external magnetic field is applied to modulate the NFRHT of magneto-optical nanoparticles [52-55] and plates [56, 57]. The unique phenomena caused by magnetic field are mainly attributed to the anisotropic permittivity of InSb. In addition, applying an external magnetic field perpendicularly to graphene induces some unique phenomena, such as quantum Faraday effects and Kerr effects [58, 59] because of the magneto-optical conductivities of graphene [60-62]. In particular, the magnetic field modulates the NFRHT between two suspended graphene sheets[63, 64]. Shubnikov–de Haas-like oscillations have been observed in the spectral heat flux caused by the intraband or interband transitions between various Landau levels (LLs). For a strong magnetic field, an additional band with the resonant peak appearing at near-zero frequency exists, which has never been found in graphene systems at such a low frequency before.

The surface characteristics of objects can be anisotropic when they are patterned into metasurfaces or gratings. In the near-field regime, the heat transfer can be modulated in a mechanical method by changing the
twisted angle between the optical axes of the two anisotropic surfaces [65-69]. Considering this phenomenon, we combine the effects of twist and magnetic field in the present study to modulate the NFRHT between two graphene gratings. The paper is structured as follows. In Section II, the anisotropic magneto-optical conductivity of graphene gratings, reflection coefficients and energy transmission coefficients are introduced. In Section III, the NFRHT between two parallel gratings in the presence of a magnetic field is investigated. The effects of graphene filling factor and magnetic field on NFRHT are investigated. Then, in the absence of a magnetic field, the effect of twist on NFRHT is studied for different graphene filling factors. In Section IV, the combined effect of twisted angle and magnetic field is studied simultaneously. Finally, in Section V, we provide conclusive remarks.

II. PHYSICAL SYSTEM

A. NEAR-FIELD RADIATIVE HEAT TRANSFER

![Schematic of NFRHT between two twisted graphene gratings](image)

Fig. 1. Schematic of NFRHT between two twisted graphene gratings composed of arrays of strips, whose periodicity and width are \(L\) and \(L_g\), respectively. The vacuum distance between them is denoted as \(d\). The two sheets are kept at temperature \(T_1\) and \(T_2\). The main axes of the two gratings are labeled with the blue and red-dashed lines with twisted angle \(\theta\). A magnetic field \(B\) is applied perpendicularly to the gratings.

We consider a system composed of two parallel graphene gratings separated by a vacuum gap with separation distance \(d\). The two graphene gratings are composed of arrays of graphene strips with the periodicity \(L\) and the strip widths \(L_g\), as illustrated in Fig. 1. The temperatures of the two gratings are denoted as \(T_1\) and \(T_2\). The two gratings are twisted, and the twisted angle \(\theta\) is represented by the main axes of the two gratings, which are labeled with blue and red dashed lines. An external magnetic field \(B\) is applied perpendicularly to the graphene gratings. The net radiative heat flux between two graphene sheets is given by
\[ \Phi = \int_0^\infty \frac{d\omega}{2\pi} \varphi(\omega) \]  
(1)

where the monochromatic heat flux is

\[ \varphi(\omega) = \frac{\hbar n_{1,2}^2}{4\pi^2} \int_0^\infty \zeta(\omega, \kappa) \kappa d\kappa \]  
(2)

where \( \hbar \) is Planck’s constant divided by 2\( \pi \) and \( n_{1,2}(\omega) = n_1(\omega) - n_2(\omega) \) denotes the difference between the two mean photon occupation numbers \( n_{1,2}(\omega) = \left[ \exp(\hbar \omega / k_B T_{\text{vac}}) - 1 \right]^{-1} \). \( \kappa \) is the component of the wave vector parallel to the interface. \( \zeta(\omega, \kappa) \) is the energy transmission coefficient, which reads \([66, 69, 70]\)

\[
\zeta(\omega, \kappa) = \begin{cases} 
\text{Tr} \left[ \left( I - R_j^i R_j^t - T_j^i T_j^t \right) \mathbf{D}_{12} \left( I - R_j^i R_j^t - T_j^i T_j^t \right) \mathbf{D}_{ij} \right], & \kappa < \kappa_0 \\
\text{Tr} \left[ \left( R_j^i R_j^t \right) \mathbf{D}_{12} \left( R_j^i R_j^t \right) \mathbf{D}_{ij} \right] e^{-2\kappa|\mathbf{t}|}, & \kappa > \kappa_0
\end{cases}
\]  
(3)

where \( \kappa_0 = \omega c / \kappa_0 \) is the wave vector in vacuum, \( \kappa_z = \sqrt{\kappa_0^2 - \kappa^2} \) is the normal component of the wave vector in vacuum. \( \mathbf{D}_{ij} = \left( I - R_j e^{2i\kappa|\mathbf{t}|} \right)^{-1} \) is the Fabry-Perot-like denominator matrix and \( R_j (j=1, 2) \) is the reflection coefficient matrix for the \( j \)-th graphene grating, with the form

\[
R_j = \begin{bmatrix} r_j^{ss} & r_j^{sp} \\
 r_j^{ps} & r_j^{pp} \end{bmatrix}
\]  
(4)

where the superscripts \( s \) and \( p \) represent the polarizations of transverse electric and transverse magnetic modes, respectively. The reflection coefficients of graphene sheets coated on an isotropic substrate are given by \([63, 64, 71]\)

\[
\begin{align*}
 r_j^{ss} &= \frac{(\rho_a + 1)(1 - \rho_c) + \rho_b \rho_d}{(\rho_a + 1)(\rho_c + 1) - \rho_b \rho_d} \\
 r_j^{sp} &= \frac{2\rho_b}{(\rho_a + 1)(\rho_c + 1) - \rho_b \rho_d} \\
 r_j^{ps} &= \frac{-2\rho_d}{(\rho_a + 1)(\rho_c + 1) - \rho_b \rho_d} \\
 r_j^{pp} &= \frac{(\rho_a - 1)(1 + \rho_c) - \rho_b \rho_d}{(\rho_a + 1)(\rho_c + 1) - \rho_b \rho_d}
\end{align*}
\]  
(5)

where \( \rho_a = \left( \sigma_{xx} / \omega \varepsilon_0 + \varepsilon_i / \kappa_{z,i} \right) \kappa_z \), \( \rho_b = \sqrt{\mu_0 / \varepsilon_0} \sigma_{xy} \), \( \rho_c = \left( \sigma_{yy} \omega \mu_0 + \kappa_{z,i} / \kappa_z \right) / \kappa_z \) and \( \rho_d = \sqrt{\mu_0 / \varepsilon_0} \sigma_{yy} \). \( \varepsilon_i \) and \( \mu_0 \) are the permittivity and permeability of vacuum, respectively. \( \kappa_{z,i} = \sqrt{\varepsilon_i \kappa_0^2 - \kappa^2} \) is the normal component of the wave vector in the substrate with the relative permittivity \( \varepsilon_i \). The conductivities \( \sigma_{xx}, \sigma_{yy}, \sigma_{yx}, \) and \( \sigma_{yx} \) are
introduced in the following part.

B. MAGNETO-OPTICAL CONDUCTIVITY OF GRAPHENE GRATINGS

When a magnetic field is applied perpendicularly to graphene, the response of graphene electrons to the external magnetic field displays a characteristic optical quantum Hall effect [60, 72]. The conductivity of graphene becomes a tensor with nonzero values for diagonal and off-diagonal components, given by

\[
\begin{pmatrix}
\sigma_{xx} & \sigma_{xy} \\
\sigma_{yx} & \sigma_{yy}
\end{pmatrix} =
\begin{pmatrix}
\sigma_L & \sigma_H \\
\sigma_H & \sigma_L
\end{pmatrix}
\]  

(6)

where \( \sigma_L \) and \( \sigma_H \) represent the longitudinal and Hall conductivities, respectively. Within the Dirac-cone approximation [73], the magneto-optical conductivity of graphene assumes the simple form in the random phase approximation [72, 74]

\[
\sigma_{LH}(\omega, B) = g_s g_v e^2/4\hbar \sum_{n,m=-\infty}^{\infty} \frac{\Xi_{nm}^{LH}}{i\Delta_{nm}^2 + \hbar \omega + \Delta_{nm} + i\Gamma_{nm}(\omega)}
\]  

(7)

where \( g_s(\nu) = 2 \) is the spin (valley) degeneracy factor of graphene, \( e \) is the charge of an electron, and \( \hbar \) is Planck’s constant. \( n_F(E_n) = 1/[1 + e^{(E_n - \mu)/k_BT}] \) stands for the Fermi distribution function, \( k_B \) is the Boltzmann constant, and \( \mu \) and \( T \) are the chemical potential and temperature of graphene, respectively. Throughout this paper, \( T \) is fixed at 300 K unless otherwise noted. \( \Gamma_{nm}(\omega) \) is the LL broadening, taken as 6.8meV in this paper [75].

With the application of an external magnetic field, electrons acquire considerable cyclotronic energies via the Lorentz force. The continuum Dirac energy spectrum evolves into degenerated LLs with the energies of \( n \)-th LL given by

\[
E_n = \text{sign}(n)(\hbar v_F/l_B)\sqrt{2|n|}
\]  

(8)

where \( v_F \approx 10^6 m/s \) is the Fermi velocity of the carriers in graphene, \( l_B = \sqrt{\hbar/eB} \) is the magnetic length, and \( B \) is the intensity of the magnetic field. \( \Delta_{nm} = E_n - E_m \) is the LL energy transition (\( m, n = 0, \pm 1, \pm 2, \ldots \) are the LL indices). The matrix elements in Eq. (7) are given by

\[
\Xi_{nm}^{LH} = \frac{\hbar^2 v_F^2}{l_B^2} (1 + \delta_{m,0} + \delta_{n,0}) \delta_{|n|+1} \\
\Xi_{nm}^{H} = i\Xi_{nm}^{LH} (\delta_{|n|+1} - \delta_{|m|+1})
\]  

(9)

where \( \delta \) is the Kronecker symbol.

To demonstrate the quantum regime of the magneto-optical conductivity clearly, we show the schematic of
the electronic transitions of graphene for \( \mu = 0, 0.2, 0.3 \text{ eV} \) with a magnetic field \( B = 10 \text{ T} (E_1 \approx 0.11 \text{ eV}) \) in Figs. 2(a)-2(c), respectively. The figures show that the band structure of graphene is composed of two Dirac cones. The magnitudes of energy for different LLs can be regarded as the sizes of different plates in the Dirac cones. The number of last occupied LLs is denoted as \( N_F = \text{int}[\mu/E_1] \), which yields the number of occupied electron-degenerate LLs. In view of Eq. (8), \( N_F \) undoubtedly increases as the chemical potential of graphene. The electronic transitions have two types: (i) intraband transitions limited to adjacent LLs (\( N_F \) to \( N_F + 1 \)) within the positive cone; and (ii) interband transitions, connecting LLs from the negative cone with LLs in the positive cone. The allowed interband and intraband transitions are represented with the vertical arrows in blue and crooked arrows in red, respectively. As shown in Fig. 2(a), the state at \( n = 0 \) falls at the apex of the Dirac cones, where positive and negative energy cones meet. The transition involving zero-energy from \( n = 0 \) to \( n = 1 \) LLs in Fig. 2(a) is the only transition that cannot be definitely designated as inter or intraband transition. In this study, it is denoted as an interband-like transition for simplicity.

In consideration that the magneto-optical conductivity of graphene is mainly determined by the longitudinal part, the real and imaginary parts of longitudinal conductivity are plotted for \( B = 10 \text{ T} \), with red and blue solid curves in Figs. 2(d)-2(f). \( \sigma_L \) is plotted as a function of \( E/E_1 \), with \( E = \hbar \omega \) and \( E_1 = \sqrt{2} \hbar v_F / l_B \). The three panels are for \( \mu = 0, 0.2, 0.3 \text{ eV} \), corresponding to Figs. 2(a)-2(c). Intraband transition with an energy difference of \( \Delta_{\text{intra}} = E_{N_F + 1} - E_{N_F} \) dominates at low frequency where most of the spectral weight is centered around
\[
\omega = \left( E_{N_F + 1} - E_{N_F} \right) / \hbar = \sqrt{N_F + 1 - N_F} E_1 / \hbar \quad (\text{green dashed line in Fig. 2(e)}).
\]
Interband transitions with an energy difference of \( \Delta_{\text{inter}} = E_{n+1} + E_n (n \geq N_F) \) have a series of peaks at frequency
\[
\omega = \left( E_{n+1} + E_n \right) / \hbar = \sqrt{n + 1 - n} E_1 / \hbar \quad (\text{blue dashed lines beyond the interband threshold} \ E \simeq 2 \sqrt{N_F E_1} \text{ (violet dashed lines in Figs. 2(e) and (f))}).
\]
A series of absorption peaks demonstrating the maxima of the real part and 0 for the imaginary part at high frequencies is observed.

In view of Eq. (8) and the definitive formula of \( N_F \), \( N_F \) decreases as the magnetic field \( B \) increases. As a result, no intraband transitions can occur at a low electronic density or strong magnetic field (large \( E_1 \), i.e., \( \mu = 0 \text{ eV} < E_1 \approx 0.11 \text{ eV} \)). The magneto-optical conductivity is completely determined by the interband transitions. For a high electronic density of \( \mu = 0.2 \text{ eV} \) between \( E_3 \) and \( E_4 \) as shown in Fig. 2(e), some low-frequency interband transitions vanish and intraband transitions emerge. For a higher electronic density of \( \mu = 0.3 \text{ eV} \) as shown in Fig. 2C, the real and imaginary parts of longitudinal conductivity are plotted for \( B = 10 \text{ T} \), with red and blue solid curves in Figs. 2(d)-2(f). \( \sigma_L \) is plotted as a function of \( E/E_1 \), with \( E = \hbar \omega \) and \( E_1 = \sqrt{2} \hbar v_F / l_B \). The three panels are for \( \mu = 0, 0.2, 0.3 \text{ eV} \), corresponding to Figs. 2(a)-2(c). Intraband transition with an energy difference of \( \Delta_{\text{intra}} = E_{N_F + 1} - E_{N_F} \) dominates at low frequency where most of the spectral weight is centered around
\[
\omega = \left( E_{N_F + 1} - E_{N_F} \right) / \hbar = \sqrt{N_F + 1 - N_F} E_1 / \hbar \quad (\text{green dashed line in Fig. 2(e)}).
\]
Interband transitions with an energy difference of \( \Delta_{\text{inter}} = E_{n+1} + E_n (n \geq N_F) \) have a series of peaks at frequency
\[
\omega = \left( E_{n+1} + E_n \right) / \hbar = \sqrt{n + 1 - n} E_1 / \hbar \quad (\text{blue dashed lines beyond the interband threshold} \ E \simeq 2 \sqrt{N_F E_1} \text{ (violet dashed lines in Figs. 2(e) and (f))}).
\]
A series of absorption peaks demonstrating the maxima of the real part and 0 for the imaginary part at high frequencies is observed.
2(f), the interband threshold is so large that interband transitions decay greatly. In this case, intraband transitions dominate the magneto-optical conductivity of graphene. In sum, the response of graphene electrons to the external magnetic field has two regimes: (i) the semiclassical limit, for low magnetic field and/or high electronic density; and (ii) the quantum Hall regime, for strong magnetic field and/or low electronic density.

Fig. 2. Schematic of Dirac cones and different LLs in a magnetic field \( B=10T \) (\( E_1=0.11 \text{ eV} \)) for (a) \( \mu=0 \text{ eV} \), (b) 0.2 eV and (c) 0.3 eV: The energies of the LLs are shown for different indices \( n \) as red disks for both positive and negative Dirac cones, with the allowed interband transitions (vertical arrows in blue) and intraband transitions (crooked arrows in red). (d)-(f): The longitudinal conductivity of graphene \( \sigma_L \) as a function of \( E/E_1 \), with \( E=\hbar \omega \) and \( E_1=\sqrt{2}\hbar v_F / l_B \) for (d) \( \mu=0 \text{ eV} \), (e) 0.2 eV and (f) 0.3 eV; (g)-(i): \( \text{Im}[\sigma_\parallel] \) and \( \text{Im}[\sigma_\perp] \) with strip periodicity \( L=20 \text{ nm} \), filling factor \( f_g=0.5 \) for (g) \( \mu=0 \text{ eV} \), (h) 0.2 eV and (i) 0.3 eV.

For two twisted graphene gratings, the conductivity tensor should be modified by the effective conductivity \[76\]

\[
\begin{pmatrix}
\sigma_{xx} & \sigma_{xy} \\
\sigma_{yx} & \sigma_{yy}
\end{pmatrix} = \begin{pmatrix}
\sigma_\parallel \cos^2 \varphi_j + \sigma_\perp \sin^2 \varphi_j & \sigma_\parallel \sin \varphi_j (\sigma_\parallel - \sigma_\perp) \cos 2\varphi_j / 2 \\
-\sigma_\parallel \cos \varphi_j (\sigma_\parallel - \sigma_\perp) \sin 2\varphi_j / 2 & \sigma_\perp \sin^2 \varphi_j + \sigma_\parallel \cos^2 \varphi_j
\end{pmatrix} \quad (10)
\]
where the effective conductivities along ($\sigma_\parallel$) and across ($\sigma_\perp$) the main axis, and effective Hall conductivity $\sigma_{\text{H}}^{\text{eff}}$ are given by [76]

$$\sigma_\perp = \sigma_L \sigma_c / (f_g \sigma_c + f_c \sigma_L) \quad (11)$$

$$\sigma_{\text{H}}^{\text{eff}} = f_g \sigma_\perp / \sigma_L \quad (12)$$

$$\sigma_\parallel = f_g \sigma_L + f_c \sigma_\perp^2 / \sigma_L - \left(\sigma_{\text{H}}^{\text{eff}}\right)^2 \sigma_\perp \quad (13)$$

where $f_g = L_g / L$ is the graphene filling factor, and $f_c = 1 - f_g$ is the filling factor of the free space between adjacent strips. $\sigma_c = -i \omega \varepsilon_{\text{eff}} \frac{L}{\pi} \ln \left[ \csc \left( \frac{\pi f_c}{2} \right) \right]$ [77] is an equivalent conductivity associated with the near-field coupling between adjacent strips, where $\varepsilon_{\text{eff}}$ denotes the relative permittivity of the dielectric medium surrounding graphene.

For two suspended graphene sheets or gratings, $\varepsilon_{\text{eff}}$ equals 1.

For the strip periodicity $L = 20$ nm and graphene filling factor $f_g = 0.5$, the imaginary parts of anisotropic optical conductivities for orthogonal directions ($\sigma_\parallel$ and $\sigma_\perp$) are plotted with blue and red lines in Figs. 2(g)-2(i) for $\mu = 0$, $0.2$, and $0.3$ eV, respectively. Only when $\text{Im}[\sigma_\parallel]$ is positive can graphene SPPs work. For low chemical potentials ($\mu = 0$ eV), the magneto-optical conductivity of graphene gratings also reveals the multiband spectrum. Moreover, they match well with the frequencies defined by the interband transitions, represented by blue dashed lines. No essential changes are observed in the magneto-optical conductivity of graphene gratings, except that they convert to anisotropy. However, for larger chemical potentials of $\mu = 0.2$ eV and $0.3$ eV when intraband transitions dominate, below the interband threshold, the effective conductivities are similar to those of graphene gratings in the absence of a magnetic field [21]. The oscillations of $\text{Im}[\sigma_\parallel]$ at high frequencies above the interband threshold imply that the interband transitions are not greatly affected by grating. The phenomenon implies that the magnetic field exerts minimal effect on conductivities when graphene is patterned into gratings for high electronic density. In other words, for large chemical potentials, the pattern transformation from sheets to gratings renders the magneto-optical conductivity of graphene impossible to exhibit. Therefore, investigating the NFRHT for graphene gratings with high chemical potentials is unnecessary.

### III. RESULTS AND DISCUSSION

To ensure the accuracy of the calculations based on the effective medium theory (EMT), the vacuum gap distance $d$ should be several times larger than the strip periodicity. As given by Ref [21], for $L = 20$ nm, the
EMT predicts the real heat flux well when \( d \geq 60 \) nm. In the following results, the parameters are selected as \( d=60 \) nm, \( L=20 \) nm, \( T=300 \) K unless otherwise noted. \( \phi \) in Eq. (10) denotes the azimuthal angle of the main axis for grating \( j \) (\( j=1, 2 \)), which is illustrated in Fig. 1. When the gratings are aligned, the relationship of azimuthal angles for the two gratings is \( \phi_2=-\phi_1 \). If a twisted angle \( \theta \) exists between the two gratings, then \( \phi_2=\phi_1+\theta \) [70]. In view of Eqs. (4)–(5) and (10), integration over azimuthal angles is necessary for the energy transmission coefficients because Fresnel’s coefficients and conductivity of graphene gratings depend on \( \phi \). Hence, the energy transmission coefficients considering the integration over azimuthal angles are given as

\[
\xi(\omega, \kappa) = \frac{1}{2\pi} \int_{0}^{2\pi} \xi(\omega, \kappa, \phi) d\phi
\] (14)

In particular, when \( f_g=1 \), our results match well with those for two magnetic graphene sheets [63, 64]. When \( f_g<1 \), \( B=0 \) T and twisted angle \( \theta=0^\circ \), we can obtain the same results as those for graphene gratings in the absence of a magnetic field [21]. In the following discussion, the radiative heat transfer coefficient (RHTC) is utilized to evaluate the NFRHT between two twisted graphene gratings as

\[
h = \frac{\Delta D}{\Delta T} = \frac{1}{8\pi} \int_{0}^{e} \int_{0}^{2\pi} \xi(\omega, \kappa, \phi) \kappa d\kappa d\phi
\] (15)

A. PARALLEL GRATINGS IN MAGNETIC FIELD

Fig. 3. (a) RHTCs corresponding to different sets of \((B, \mu)\) with \( f_g=0.5 \); (b) RHTC modulation factor of magnetic fields \( \eta(B)=(h(B, \mu)-h(0, \mu))/h(0, \mu) \) for different \( \mu \).

The effect of magnetic field on heat transfer between two parallel gratings is studied. The RHTCs corresponding to different sets of \((B, \mu)\) are given in Fig. 3(a) for parallel gratings with graphene filling factor \( f_g=0.5 \). The results reveal notable differences for different chemical potentials of graphene. The maximum RHTC is reached around \( \mu=0.15–0.2 \) eV, and its trend varies with magnetic field at different \( \mu \). The modulation factor of magnetic fields is defined as \( \eta(B)=(h(B, \mu)-h(0, \mu))/h(0, \mu) \) to demonstrate the modulation effect of magnetic field
The results of $\eta(B)$ for different chemical potentials are given in Fig. 3(b). The magnitude of $\eta(B)$ can reflect the changes in RHTC in the presence of a magnetic field, which is viewed as the modulation ability of the magnetic field. The gradients of the $\eta(B)$ curves at different $B$ values are regarded as the modulation speed for the specific magnetic field. The first glimpse of the $\eta(B)$ results reveals the general trend that the modulation ability of the magnetic field is weakened as the chemical potentials increase. For $\mu=0.04$ eV, the heat transfer is greatly weakened due to the presence of a magnetic field. $\eta(B)$ monotonically decreases as the magnetic field when $\mu$ is 0 eV and 0.01 eV. Moreover, the modulation speed of the magnetic field decays as $B$ increases. $\eta(B)$ has a much lower magnitude at $\mu=0.1$, 0.2, 0.3 eV than at lower chemical potentials. The magnetic field has almost no effect on RHTC when $\mu=0.3$ eV. This result is mainly attributed to the failure of the magnetic field to lead to the magneto-optical conductivity for graphene gratings, as observed in Fig. 2. The above results indicate that the modulation effect of magnetic field has different levels and trends corresponding to different $\mu$. The heat transfer can be greatly influenced by the magnetic field when the chemical potentials of graphene are low, especially for $B=0$–5 T. For this reason, our research results are mainly focused on the low chemical potentials of graphene $\mu=0.01$ eV.

**Fig. 4.** (a) Energy transmission coefficients, (b) spectral RHTC and (c) Im[ $\sigma$ || ] for different $B$ with $f=0.5$

The contours of energy transmission coefficients for different $B$ are given in Fig. 4(a) to explain the modulation effect of magnetic field. For zero-field in Fig. 4(a-1), the energy transmission coefficients occupy a
whole \( \omega \cdot \kappa \) area, which is similar to that of two suspended graphene sheets. Then, they are converted to two separated parts when a magnetic field is applied. In fact, energy transmission coefficients split into multiband spectra in higher frequency. However, they are so weak that we do not demonstrate them here. As \( B \) increases, the low-frequency modes gradually decay to a narrow band, and they are given in separate panels in Figs. 4(a)-4(a-6).

To demonstrate the trend of high-frequency and low-frequency modes clearly, the spectral RHTCs for \( B=5, 10, 15 \) T are given in Fig. 4(b). When \( B \) is higher than 5 T, the low-frequency modes become near-zero modes, as demonstrated in magnetic graphene sheets [64]. The near-zero modes gradually become stronger and the band becomes wider as \( B \) increases. Instead, the high-frequency modes gradually attenuate and show a blue shift at the same time. The larger modulation speed observed in Fig. 3(b) for \( B=0-5 \) T is mainly caused by the simultaneous attenuation of the two modes, whereas the high-frequency and near-zero modes have different trends for larger \( B \) (5–15 T). Fig. 4(c) shows a plot of the imaginary part of effective conductivities along the main axis \( \text{Im}[\sigma_\parallel] \) to explain the existence of near-zero modes and the blue shift of high-frequency modes. \( \text{Im}[\sigma_\parallel] \) remains negative in the whole frequency regime of interest for different \( B \); thus, it is not given in the plot. Only when \( \text{Im}[\sigma_\parallel] \) and \( \text{Im}[\sigma_\perp] \) are positive and negative, respectively, can hyperbolic graphene SPPs work. As shown in Fig. 4(c), the zero points for \( B=5, 10, 15 \) T are marked with dashed lines together with arrows and are added to the energy transmission coefficient contour. The blue shift can be explained by the trend of \( \text{Im}[\sigma_\parallel] \) with respect to increasing \( B \). The inset in Fig. 4(c) denotes the local enlarged drawing of \( \text{Im}[\sigma_\parallel] \) near zero-frequency. It demonstrates that \( \text{Im}[\sigma_\parallel] \) is positive in a narrow band near zero-frequency for larger \( B \).

![Fig. 5. (a): RHTCs corresponding to different sets of \((B, f_g)\); (b): RHTC modulation factor of graphene filling factor \( \eta(f_g)=(h(B, f_g)-h(B, 1))/h(B, 1) \) for different \( B \)](image)

For two parallel gratings, the graphene filling factor greatly influences heat transfer. To study the effect of
the graphene filling factor $f_g$ together with the magnetic field $B$, we provide the RHTCs corresponding to different sets of $(B, f_g)$ in Fig. 5(a). In the presence of a weak magnetic field, the maximum RHTC is reached when $f_g=1$, which means graphene sheets. Moreover, for different $f_g$, the RHTC decreases with increasing $B$. The detailed results are given by the modulation factor of magnetic fields $\eta (B)$ in the inset of Fig. 5(a). The modulation speed of magnetic field decays dramatically at large $B$, especially for low $f_g$. The modulation effect of the magnetic field for gratings is greater than that for graphene sheets when $f_g$ is lower than 0.4. Interestingly, the modulation effect of the magnetic field is greater for lower $f_g$ when graphene sheets are patterned into gratings. This result is mainly attributed to the combined effect of anisotropic optical conductivities in orthogonal directions, which are dependent on the magnetic field. To demonstrate the effect of $f_g$ clearly, we plot $\eta (f_g)=(h(B, f_g)-h(B,1))/h(B,1)$, defined as the the modulation factor of graphene filling factor, as a function of $f_g$ for different $B$ in Fig. 5(b). The results show clearly that the magnetic field can tune the effect of graphene filling factor on modulating NFRHT. For zero-field, $\eta (f_g)$ ranges from -0.8 to 0, but it has a wider range when a magnetic field is applied. The modulation range increases by nearly 19% when $B$ increases from 0 to 5 T and increases slightly when $B$ is larger than 5 T. The larger modulation range results from a higher modulation ability for heat transfer when the magnetic field and grating effect both work. As shown in Fig. 5(b-1), the modulation effect of $f_g$ is greater for larger $B$ at low $f_g$ (0–0.9) in the presence of a weak magnetic field. Nevertheless, for large $f_g$ (0.9–1), the $\eta (f_g)$ curves for different $B$ are nearly in coincidence. It means that the grating effect dominates the heat transfer and that the effect of magnetic field loses efficacy when graphene strips greatly occupy the grating configuration. In Fig. 5(b-2), the $\eta (f_g)$ curves have different trends with growing $B$, when the effect of the magnetic field is greater than that of the weak magnetic field. As $B$ increases, the modulation speed of $f_g$ increases at low $f_g$ (0.1–0.8) and decays at large $f_g$ (0.8–1). Interestingly, $\eta (f_g)$ non-monotonically increases with $f_g$, especially in the presence of a strong magnetic field, and its maximum value exists at around $f_g=0.7$ for $B=15$ T. A similar phenomenon is observed for two parallel graphene gratings in the absence of a magnetic field for $\mu=0.5$ eV in Ref. [20]. However, the optimal $f_g$ observed in Ref. [20] is different from the maximum $\eta (f_g)$. The unique phenomenon is caused by the combined effect of magnetic field and grating, and the physical mechanism is discussed in the following part in detail.
Fig. 6. (a) Spectral RHTCs, (b) Im[σ] and (c) energy transmission coefficients for different $f_g$ with $B=15$ T

The spectral results for different $f_g$ with $B=15$ T are given in Fig. 6(a) to explore the physical mechanism of the grating effect clearly. When graphene sheets are patterned into strips, the near-zero peak greatly increases and the band becomes wider as $f_g$ decreases. Moreover, the high-frequency peak is converted into two parts, and they have different trends with $f_g$. To intuitively explain the two modes, we plot the imaginary parts of anisotropic optical conductivities for orthogonal directions in Fig. 6(b). Only when Im[σ∥] is positive can graphene SPPs work, which is denoted by the red vertical line. Hyperbolic and elliptic modes come into play when Im[σ⊥] is negative and positive, respectively. The bands of hyperbolic and elliptic modes are labeled with vertical lines in Fig. 6(b). On the right side of the red vertical line, the dividing point between hyperbolic and elliptic modes are denoted with the blue and violet vertical lines for $f_g=0.9$ and 0.85, respectively. As $f_g$ decreases, the position of the dividing point shows a blue shift and Im[σ⊥] for the elliptic modes is very close to zero when $f_g=0.7$. According to the above phenomenon, the two parts observed in Fig. 6(a) are hyperbolic and elliptic graphene SPPs modes. The contours of energy transmission coefficients for different $f_g$ are given in Fig. 6(c) to verify the two modes. The contours match with the change trend of spectral RHTC. Using the relationships $\xi(\omega, \kappa, \phi) = \xi(\omega, \kappa_x, \kappa_z)$,
\( \kappa_x = \kappa \cos \phi \), and \( \kappa_y = \kappa \sin \phi \), we provide the anisotropic energy transmission coefficients for the specific frequencies in panels (i)–(iii). The dispersion relations are represented with green dashed lines, which are calculated by zeroing the denominator of Eq. (5). The frequencies of panels (i)–(iii) are indicated with dashed lines in Figs. 6(c-1) and (c-2). For \( f_g = 1 \), which means graphene sheets (\( \text{Im}[\sigma_x] \) and \( \text{Im}[\sigma_y] \) are in coincidence in Fig. 6(b), the energy transmission coefficients are isotropic in panel (i). Panels (ii) and (iii) verify that the low-frequency and high-frequency modes are hyperbolic and elliptic graphene SPPs modes, respectively. Elliptic SPP modes are observed in the graphene system for the first time, which is caused by magnetic field and grating simultaneously. Moreover, according to Figs. 6(a) and 6(c), as \( f_g \) decreases, the hyperbolic modes gradually enlarge and the peak position is nearly unchanged, whereas the elliptic modes dramatically weaken and show a blue shift. When \( f_g = 0.7 \), the elliptic modes almost vanish. The attenuation and blue shift of the elliptic modes are attributed to the positive–negative transition and the zero point of \( \text{Im}[\sigma_y] \) observed in Fig. 6(b), respectively. The local maximum \( \eta(f_g) \) observed in Fig. 5(b) can be well explained by the enhancement of near-zero modes and high-frequency hyperbolic modes. When \( f_g \) is lower than 0.7, the near-zero modes and high-frequency hyperbolic modes both decay as \( f_g \) decreases, which is not demonstrated in the figure.

**B. TWISTED GRATINGS WITHOUT MAGNETIC FIELD**

![Fig. 7](image-url) In the absence of magnetic fields, RHTC modulation factor of (a) twisted angle \( \theta \) and (b) graphene filling factor \( f_g \)

In this section, the effect of twist between two graphene gratings on heat transfer is investigated in the absence of a magnetic field. The RHTC modulation factors of twisted angle \( \eta(\theta) = (h(f_g, \theta) - h(f_g, 0))/h(f_g, 0) \) are given in Fig. 7(a) for different \( f_g \). The results reveal a strictly monotonic decreasing of \( \eta(\theta) \) as \( \theta \) is increased from 0° to...
90°, which is mainly attributed to the symmetry breaking caused by the twisting effect of gratings. The similar attenuation of heat transfer caused by twist has been observed in other NFRHT systems [64-66, 68, 69], and they are all explained by the breaking of symmetry between two anisotropic surfaces. \( \eta (\theta) \) ranges from 0 to -0.65 and -0.58 for \( f_g=0.1 \) and \( f_g=0.25 \), respectively. The \( \eta (\theta) \) curves are basically in coincidence when \( f_g \) is between 0.4 and 0.7. However, for larger \( f_g \), the modulation range of \( \eta (\theta) \) decreases and reduces to zero when the gratings convert into sheets (\( f_g=1 \)). When \( f_g \) is less than 1, the reflection characteristics of the two gratings are anisotropic. Hence, the heat transfer is greatly dependent on the matching degree of the two interfaces, which is dependent on the twisted angle \( \theta \). As a result, twist action can largely reduce the heat transfer between the two graphene gratings. For large graphene filling factors, which means the grating configuration is mostly occupied by graphene strips, the anisotropy of graphene conductivity is so weak that the matching degree of the two interfaces is weakly influenced by the twisted angle. In Fig. 7(b), RHTC modulation factors of graphene filling factor \( \eta (f_g) = (h(f_g, \theta) - h(1, \theta))/h(1, \theta) \) are given for different twisted angles. When the two graphene gratings are parallel (\( \theta=0^\circ \)), \( \eta (f_g) \) ranges from -0.8 to 0. When the graphene gratings are twisted (\( \theta \neq 0^\circ \)), the modulation range of \( \eta (f_g) \) is increases as the twisted angle \( \theta \) increases. At different \( f_g \), the modulation ability of \( f_g \) is always greater for larger \( \theta \), which means the twist action can contribute to the modulation ability of \( f_g \). However, the modulation speed of \( f_g \) is lower at low \( f_g \) (0.1–0.8) and higher at high \( f_g \) (0.8–1) with increasing \( \theta \). In the absence of a magnetic field, less \( f_g \) and larger \( \theta \) can lead to larger modulation ability for the twisted angle and graphene filling factor to modulate the NFRHT, respectively.
According to the conductivity for $B = 0$ T in Fig. 4(c), the graphene SPPs modes are hyperbolic in the absence of a magnetic field when graphene is patterned into gratings. Spectral RHTC and anisotropic energy transmission coefficients for different $\theta$ with $f_g = 0.5$ are given in Fig. 8 to reveal the underlying mechanism of the attenuation caused by twist. The spectral RHTC obviously reveals that the radiative heat transfer becomes weaker as the twisted angle increases. Although the peak of spectral RHTC slightly increases for large $\theta$ ($75^\circ$, $90^\circ$), it is decreasing in most part of the spectrum and the total heat transfer is reducing. In Fig. 8(b), the red and green dashed lines denote the dispersion relations of the two graphene gratings. Clearly, they are in coincidence for $\theta = 0^\circ$, which means the reflection characteristics of the two gratings are in good agreement. The contours show that the anisotropic energy transmission coefficients reach the maximum where the two dispersion relation curves intersect. The mismatch between the two dispersion relation curves of the two gratings increases as the twisted angle increases. Hence, the anisotropic energy transmission coefficients gradually decay and then the heat transfer is undoubtedly weakened.

C. COMBINED EFFECT OF MAGNETIC FIELD AND TWIST
In this section, the effects of magnetic field and twist are investigated simultaneously to reveal their combined effect. Fig. 9 has the same form as Fig. 7, whereas the magnetic field is applied to the graphene gratings this time and $B=15$ T. Similar to the modulation performance in the absence of a magnetic field, less $f_g$ and larger $\theta$ also cause larger modulation range of $\theta$ and $f_g$ for heat transfer when a magnetic field is applied. Comparing the results of $\eta(\theta)$ in Figs. 7(a) and 9(a), magnetic field endows the twist action with a higher modulation range of heat transfer for different graphene filling factors. In particular, the curves for high graphene filling factors $f_g=0.85$ and 0.91 demonstrate much higher modulation range than those in the absence of a magnetic field. The underlying mechanism is introduced in the next part. The curves in Fig. 9(b) provide the results of $\eta(f_g)$ for different twisted angles. In comparison, $\eta(f_g)$ for different twisted angles have larger modulation range than zero-field, especially for small twisted angles. Compared with the results in Fig. 7(b), the twisted angle has a greater influence on $f_g$ to modulate the NFRHT when a magnetic field is applied. Similar to the zero-field results, the modulation speed of $f_g$ is lower at low $f_g$ (0.1–0.8) and higher at high $f_g$ (0.8–1) with increasing $\theta$. Moreover, the local maximum $\eta(f_g)$ at $f_g=0.7$ gradually disappears as $\theta$ increases.
In Fig. 10, the detailed results considering magnetic field and twist are given. For \( f_g = 0.5 \), the RHTCs corresponding to different sets of \((B, \theta)\) are given in Fig. 10(a). Same as the results in the absence of a magnetic field, RHTC decreases with increasing twisted angle for different \( B \). This result can be preliminarily explained by the growing mismatch of reflection characteristics between two twisted gratings. In addition, RHTC still decays when the magnetic field strength increases for different twisted angles. To demonstrate the effect of twist clearly, we plot the modulation factors of twisted angle \( \eta(\theta) \) for different magnetic fields in Fig. 10(b-1). The results reveal an obvious difference in \( \eta(\theta) \) between zero-field and non-zero-field, which is caused by their different modes. Moreover, the modulation range is widened as \( B \) increases and is nearly unchanged when \( B \) is larger than 10 T. The \( \eta(\theta) \) curves are nearly in coincidence when \( \theta \) is lower than 45°, which means the modulation ability of
twist is basically the same for small twisted angles. The results reveal that the magnetic field can hardly tune the modulation ability of twist at small $\theta$ for small $f_g$. To obtain insights into the attenuation caused by twist, we plot the spectral RHTC for $B=15$ T in Fig. 10(b-2) for $\theta=0^\circ$, $30^\circ$, $60^\circ$, and $90^\circ$. The near-zero modes and high-frequency hyperbolic modes decay as the twisted angle increases. When graphene strips greatly occupy the grating configuration, for example, $f_g=0.9$, when hyperbolic and elliptic modes exist, the $\eta(\theta)$ and the results of spectral RHTC for $B=15$ T are given in Figs. 10(c-1) and 10(c-2), respectively. The results of $\eta(\theta)$ show that the modulation ranges for different $B$ are all larger than that of zero-field. Moreover, similar to $f_g=0.5$, the modulation range is gradually enlarging with increasing $B$. In particular, the modulation range for $B=15$ T is larger than nearly half that of zero-field. Different from the results of $f_g=0.5$, the $\eta(\theta)$ curves differ from each other at different $\theta$, and the modulation ability at different $\theta$ is greater for larger $B$, which means the modulation ability of twist can be tuned by the magnetic field at different twisted angles. The above results clearly confirm that the modulation ability of twist to tune the NFRHT can be greatly enhanced by the magnetic field. The spectral results in Fig. 10(c-2) demonstrate that the near-zero, high-frequency hyperbolic, and elliptic modes decay as the twisted angle increases. To explain the attenuation trend caused by twist in the presence of a magnetic field, we provide the anisotropic energy transmission coefficients in Figs. 10(d) and 10(e) for different $\theta$ with $f_g=0.9$ and $B=15$ T. The frequencies of the first and second columns are respectively 0.15 eV / $h$ and 0.18 eV / $h$, which are the frequencies of the two peaks in Fig. 10(c-2). The red and green dashed curves denote the dispersion relations for the upper and bottom graphene gratings, respectively. The energy transmission coefficients achieve the maximum near the intersections of the two curves. As a result, for $\theta=0^\circ$, energy transmission coefficients are the largest because the dispersion relations are a perfect match. When $\theta$ is larger than $0^\circ$, the mismatch between the two dispersion relations increases and the energy transmission coefficients decrease accordingly. In comparison with the results of $f_g=0.5$, the greater modulation abilities of twist for $f_g=0.9$ are mainly caused by the simultaneous attenuation of the near-zero modes, high-frequency hyperbolic modes, and elliptic modes.

IV. CONCLUSION

We have systematically studied the NFRHT between two twisted graphene gratings based on the quantum Hall regime of magneto-optical graphene. For large chemical potentials, the pattern transformation from sheets to gratings weakens the magneto-optical characteristics of graphene. As a result, the NFRHT between graphene gratings can be greatly influenced by magnetic field only with low electronic density, which reveals the quantum
Hall regime. Three graphene SPP modes are observed in the system: near-zero modes, high-frequency hyperbolic modes, and elliptic modes. However, only hyperbolic modes work in the graphene grating system without a magnetic field. Elliptic SPP modes are observed in the graphene system for the first time, which is caused by the combined effect of magnetic field and grating. In addition, the near-zero peak can be greatly enhanced by grating and magnetic field, rendering graphene devices a promising candidate for the thermal communication at ultra-low frequency.

Analysis of the effects of magnetic field, twisted angle, and graphene filling factor on the NFRHT reveals some unique phenomena. The following conclusions are obtained. (i) The magnetic field can tune the effect of graphene filling factor on modulating NFRHT. In addition, the modulation range of graphene filling factor enlarges with increasing $B$. (ii) The attenuation of heat transfer caused by twist is mainly attributed to the symmetry breaking of the surface characteristics of the two gratings, either in the absence or presence of a magnetic field. (iii) The magnetic field endows the twist action with a high modulation range of heat transfer, especially for large graphene filling factors when elliptic and hyperbolic modes exist. (iv) The modulation ability of the magnetic field is greater for lower graphene grating filling factors and nearly unchanged for different twisted angles. The combined effect of magnetic field and twist provides graphene devices with a tunable way to realize energy modulation and multi-frequency thermal communications.
