Abstract

We describe by NG2 (neuron-glia chondroitin sulphate proteoglycan 2) immunocytochemistry an uneven distribution of NG2 glial cells in the rat cerebellum, being them more represented in the central lobules of the cerebellar vermis, belonging to the cerebrocerebellum. The cerebellar distribution of NG2 cells changes in aging rats, in which the area where the cells appear to be densely scattered throughout all cerebellar layers involves also more rostral and caudal lobules. In addition, in aging rats, in the most rostral and caudal lobules belonging to the spinocerebellum, punctate reactant product is present at the apical pole of Purkinje cells, i.e. in the area where the majority of synapses between olivary climbing fibers and Purkinje cells occur. Data suggest that the different distribution of NG2 cells is correlated to differences in physiology among cerebellar areas and reflects changes during aging.

Introduction

NG2 cells (neuron-glia chondroitin sulphate proteoglycan 2), also referred to as synaptocytes, polydendrocytes, β-astrocytes, oligodendrocyte precursor cells (OPC) have been recognized as the fourth type of glial cells in the mammalian central nervous system, representing about 5-8% of the glial cell population. Morphologically, at light microscopy they resemble astrocytes, though their cell body is less rounded and cytoplasmic processes slender. At electron microscopy, NG2 cells show flattened nucleus with decondensed chromatin, well-represented cytoplasmic organelles and, where opposed to neurons, focal membrane densities. Opposite to astrocytes, NG2 cells do not express GFAP nor S100 protein, but express the NG2 chondroitin sulphate proteoglycan, a membrane protein with a large extracellular domain, whose function is still obscure. In the central nervous system, NG2 cells can be found in both gray and white matter and have been proposed as resident oligodendrocyte and astrocyte precursors. Actually, their number increases in the vicinity of demyelization foci in some neuropathologies and after wound insult. On the other hand, NG2 cells do not express glutamate transporters, but have calcium-permeable AMPA receptors, that cluster in apposition to nerve terminals, forming conventional synapses. This feature suggests that these cells must have a more complex function than to be a simple reservoir of oligodendrocytes or astrocytes. The cerebellum, which has a pivotal role in motor control, timing and learning, has been relatively neglected in studies concerning aging. In elderly people, movement and stability control are less efficient, with increasing fall risk and serious consequences and social costs. Here, we describe that NG2 cells are not evenly distributed in the rat cerebellum and that their distribution and morphology undergo changes during aging.

Materials and Methods

Sprague Dawley rats, aged 4 (3 animals) and 28 months (3 animals), purchased from Harlan Nossan (Correzzana, Italy) and maintained in standard conditions (12 h light/dark cycle, 23°C temperature, food and water ad libitum) for few days were used. Experiments were performed in accordance with the Italian and European Community law for the use of experimental animals and were approved by a local bioethical committee.

Animals were deeply anesthetized with chloral hydrate (0.35 mg/g body weight) and perfused transcardially with 4% paraformaldehyde in PBS. Cerella were excised, postfixed in the same fixative for 4 h and cryoprotected in 30% sucrose overnight. The cerebella were sectioned serially into 25 μm-thick sagittal sections. Two out of every 10 sections were processed for immunocytochemistry for NG2 chondroitin sulphate proteoglycan as follows. Briefly, after treatment with 3% H2O2 in 10% methanol in PBS and with 10% normal serum in PBS containing 0.1% NaN3, the sections were incubated for 1 h with 1:200 rabbit anti-calbindin (Calbiochem, San Diego, CA, USA) or 1:200 rabbit anti-NG2 chondroitin sulphate proteoglycan (Chemicon, Billerica, MA, USA). Afterwards the sections were incubated for 90 min in anti-rabbit biotinylated IgG, followed by streptavidin-HRP complex (Vectorstain Elite kit, Vector, CA, USA). The complex was revealed by 3′, 5′-diaminobenzidine tetrahydrochloride. Some adjacent sections from 28-month-old rats were processed for calbindin immunocytochemistry (with 1:500 rabbit polyclonal antibody against calbindin, Millipore, Bedford, MA, USA) and after wound insult. On the other hand, NG2 cells do not express glutamate transporters, but have calcium-permeable AMPA receptors, that cluster in apposition to nerve terminals, forming conventional synapses. This feature suggests that these cells must have a more complex function than to be a simple reservoir of oligodendrocytes or astrocytes. The cerebellum, which has a pivotal role in motor control, timing and learning, has been relatively neglected in studies concerning aging. In elderly people, movement and stability control are less efficient, with increasing fall risk and serious consequences and social costs. Here, we describe that NG2 cells are not evenly distributed in the rat cerebellum and that their distribution and morphology undergo changes during aging.

Results and Discussion

In the cerebellar vermis of 4-month-old rats, NG2 cells appear to be unevenly distributed. In lobules VI to VIII according to Larsell NG2 cells are uniformly and densely scattered in all cerebellar layers, including the white matter (WM); their long, slender cytoplasmic processes extend to form a spider web-like structure throughout all the cerebellar cortex (Figure 1a). On the contrary, in the more rostral and caudal lobules (I-VI and IX-X), NG2 cells are less represented. Only sporadic cells may be observed in the WM and the granule cell layer (IGL), the majority of cells lying in the molecular layer (ML). In addition, they appear less intensely stained than in the more central lobules (Figure 2a). In control reaction sections...
no immunostaining is present (Figure 1c).

The uneven distribution of NG2 cells may reflect differences in fiber connections among lobules. In fact, in mammals the central part of cerebellar vermis receives its main input from the cerebral cortex and is therefore called cerebrocerebellum. The anterior and posterior parts receive afferents primarily from the spinal cord and are therefore termed spinocerebellum. With regard to efferent connections, the cerebrocerebellum acts on the cerebral cortex and the spinocerebellum influences the spinal cord. In particular, the cerebrocerebellum receives information, via the corticopontine tract, about movements that are being planned and about commands that are sent out from the motor cortex. In response, it can modulate the activity of the motor cortex so that movements are performed accurately and smoothly. The high density of NG2 cells in the central lobules of the cerebellar vermis in the rat may therefore be due to a higher functional complexity of the cerebrocerebellum, which in turn requires a higher modulation from glial cells. As already mentioned, NG2 cells show conventional synapses with neurons. The functional significance of this rapid communication between neurons and NG2 cells is still obscure, but it has been suggested that through synapses NG2 cells can monitor neuronal activity and act consequently, maybe by releasing neurotrophic substances.

The distribution of NG2 cells in the cerebellar vermis of 28-month-old rats is similar to that observed in 4-month-old animals. However, the area in which NG2 cells are more represented and uniformly scattered (relative area) appears to be enlarged, involving also the lobule V and part of the lobule IX (Figure 1b). Morphometric analysis revealed that the ratio between the relative and total areas of the sections is increased by 62% in aging animals (0.32±0.01 vs 0.52±0.02, in 4- and 28-month-old rats, respectively; P<0.0001). The expansion of the cerebellar area in which NG2 cells are densely represented in aged rats is an enigmatic finding. The lobules involved belong to the spinocerebellum. The spinocerebellum is somatotopically organized as well as its afferent fibers, so that signals from different body parts are kept segregated. The spinocerebellum is involved in the maintenance of the muscle tone and plays a role in the coordination of movements of walking. Taking into consideration that, if not exercised, muscle become hypotonic with aging, it is tempting to hypothesize that the increase in NG2 cells reflects a higher demand of neurotrophic factors or control from cerebellar neurons. Obviously, this is a hypothesis that needs to be tested in animals subjected to daily exercise (treadmill walking, for instance) to maintain...
muscle tone, and that will have an unconfutable answer only when the function of NG2 cells will be fully elucidated.

In aged rats, in lobules I-IV and IX-X, NG2 cells are no more present in the IGL and WM and in the ML they appear paler (Figure 2b) than in young-adult animal. However, punctate immunoreaction product is present in correspondence with the apical pole and stem dendrite of Purkinje cells (Figure 3). The punctate reaction in lobules belonging to the spinocerebellum may represent profiles of hypertrophic NG2 cell processes that ensheath the soma and stem dendrite of Purkinje cells. This is the cell region where climbing fibers from neurons of the inferior olivary complex form the majority of synapses with Purkinje cells. The cerebellum/inferior olivary complex system plays a major role as a comparator of sensory information and motor output. Climbing fibers inform about errors in the execution of a movement, so that the cerebellum can adjust it. In this view, since climbing fibers establish synapses with NG2 cells,11 also NG2 cells could be informed and modulate Purkinje cell activity accordingly. On the other hand, it cannot be excluded that the punctate immunoreaction product represents extracellular product. In fact, the large NG2 proteoglycan ectodomain may be cleaved and released in the extracellular matrix.14 This would also explain the pale staining of NG2 cells residing in the ML in 28-month-old animals.
