Abstract. After denervation in vivo, the frog cutaneus pectoris muscle can be led to degenerate by sectioning the muscle fibers on both sides of the region rich in motor endplate, leaving, 2 wk later, a muscle bridge containing the basal lamina (BL) sheaths of the muscle fibers (28). This preparation still contains various tissue remnants and some acetylcholine receptor-containing membranes. A further mild extraction by Triton X-100, a nonionic detergent, gives a pure BL sheath preparation, devoid of acetylcholine receptors. At the electron microscope level, this latter preparation is essentially composed of the muscle BL with no attached plasmic membrane and cellular component originating from Schwann cells or macrophages. Acetylcholinesterase is still present in high amounts in this BL sheath preparation. In both preparations, five major molecular forms (18, 14, 11, 6, and 3.5 S) can be identified that have either an asymmetric or a globular character. Their relative amount is found to be very similar in the BL and in the motor endplate–rich region of control muscle. Thus, observations show that all acetylcholinesterase forms can be accumulated in frog muscle BL.

In normally innervated vertebrate skeletal muscle, acetylcholinesterase (AChE, EC 3.1.1.7) is concentrated at the motor endplate. Some of the frog junctional enzyme is localized in muscle synaptic basal lamina (BL) (20). Moreover, the asymmetric forms of AChE, composed of tetrameric protomers and a collagen-like multistranded tail (4, 6, 9, 25; see reference 19 for a review), have been shown to interact after extraction with typical BL components such as glycosaminoglycans (3), fibrous material (33), fibronectin (11), or heparan sulfate proteoglycan and laminin (29, 32). In mouse muscle, the asymmetric forms of AChE have been shown to be part of the synaptic BL (7) and may play a crucial role in cholinergic neurotransmission (14, 16, 30). The frog BL shear preparation allows a direct approach for the determination of the cellular distribution of the AChE forms between either cytoplasmic or plasmic and external cell layers. We show in this report that all AChE molecular forms, and not exclusively asymmetric forms, are contained in or associated with BL of the motor endplate–rich (MEP-r) region of frog muscle.

Materials and Methods

Frogs and BL Preparation

Experiments were performed on the paired cutaneus pectoris muscles of adult male frog, Rana temporaria L. (18–30 g body weight). The in vivo experimental procedure of Sanes et al. (28) was used to obtain muscle BL in the MEP region after degeneration and phagocytosis of muscle cell components and nerve terminals. On day 1, after tricaine methane-sulfonate (MS 222, 1 p 1000, Sandoz Ltd., Basel) anesthesia, the nerve to the right cutaneus pectoris was transected near the muscle, and a 4–7-mm nerve segment was excised. Two rectangular slabs were removed from muscle on each side of the intramuscular nerve trunk, leaving a bridge (1.5 mm wide) of damaged muscle fibers corresponding to the MEP-r region. On day 3, frogs were x-ray irradiated (100 kV, 8 mA; filtration, 1.7 mm Al; total dose, 1600 rad with 127 rad/min; from source to animal thorax, 30 cm) upon a restricted surface of the experimental hemithorax. After the operation, the frogs were kept in water tanks at room temperature (19–22°C). Bridges of BL and contralateral MEP-r regions were biopsied for analysis 15 d after surgery.

Pure BL Preparation

We purified the above described BL bridges, extracting non-BL components using a simple incubation in a detergent medium (1% Triton X-100, 0.001 M EGTA, and 0.01 M Tris-HCl, pH 7.2) with intermittent shaking at 20°C for 75 min followed by three washes in Ringer medium.

Extraction and Analysis of AChE and Its Multiple Molecular Forms

After rinsing in Ringer’s solution, pooled muscle samples (4 to 8 MEP-r regions, BL, or purified BL sheaths) were extracted at 4°C with a glass-glass conical hand homogenizer in either a one- or a two-step procedure. In the one-step method AChE was solubilized in a standard medium (1% Triton X-100, 1 M NaCl, 0.001 M EGTA, and 0.01 M Tris-HCl, pH 7.2) with or without antiproteases (21). In the two-step procedure, the first extraction was carried out in a detergent medium (1% Triton X-100, 0.001 M EGTA, 0.01 M Tris-HCl, pH 7.2). The second extraction was performed on the resulting pellet in a high salt medium (1 M NaCl, 0.001 M EGTA, 0.01 M Tris-HCl, pH 7.2). All centrifugations in these procedures were carried out at 27,000 gmax at 4°C, and tissue extracts or exudates were immediately analyzed.

AChE activity was estimated by the method of Ellman et al. (10) using acetylthiocholine (AchCh) as a substrate. The specific reversible AChE inhib-
itor BW 284 C 51 (Burroughs-Wellcome, Research Triangle Park, NC) was sometimes used to assess enzyme specificity. Analysis of AChE forms was performed on a 5–20% continuous sucrose gradient (26). Peak areas were determined only for the major forms (3.5, 6, 11, 14, and 18 S), without correction for the contributions of other minor forms, using a Komtronic computer (Komtron Bioelectronique, Velizy) and a program correcting for spontaneous nonenzymatic AcChCh hydrolysis (8).

Collagenase Treatment

Pure collagenase (Advance Biofactures Corp., Lynbrook, NY) was added (500 IU/ml) to aliquots of muscle extracts in a high salt medium (1% Triton X-100, 1 M NaCl, 1 mM CaCl2, 50 mM MgCl2, 0.01 M Tris-HCl, pH 7.2). Collagenolytic action was obtained by 30-min incubation at 20°C immediately before sedimentation analysis (3).

AChE Irreversible Inhibition In Vivo by a Methylphosphorothioate Derivative (MPT)

To evaluate the recovery of enzymes in MEP-r regions and BL, a sublethal dose (100 μg/kg) of MPT, known as a specific irreversible and cell-permeant inhibitor of AChE (32, 13), was injected into the subcutaneous lymphatic sac of experimental frogs 3 d after surgery. The animals were kept for various periods for recovery.

Acetylcholine Receptor Analysis by Binding of 125I-labeled α-Bungarotoxin (125I-α-BgTx)

MEP-r regions and BL preparations were incubated in a culture medium (24) containing 125I-α-BgTx (15–20 Ci/μg, New England Nuclear, Boston, MA) at 0.2 μg/ml for 20 min at 20°C. Then the samples were washed twice with the incubation medium and twice with a Ringer’s solution. After extraction in the standard medium, a specific irreversible toxin-AChR complex sediments as a main 9 S peak (24).

Electron Microscopy

Conventional electron microscopy was performed as described by Pinçon-Raymond and Rieger (23).

Results

Presence of All AChE Forms in Muscle MEP-r Regions and BL Preparations

Globular and Asymmetric Molecular Forms in Normal Muscle: Action of Collagenase. In extracts of cutaneus pectoris muscle obtained with the standard medium, eserine (5 × 10⁻⁴ M), which inhibits both AChE and butyrylcholinesterase, inhibited at least 95% of the hydrolysis of AcChCh. 5 μM BW 284 C 51, the selective inhibitor of AChE, inhibits this hydrolysis by ~90%, and 5 μM of isooctamethyl pyrophosphoramide (Sigma), a specific inhibitor of butyrylcholinesterase, 15%. Thus, under standard conditions most of AcChCh hydrolysis is due to specific AChE. The sedimentation analysis of the extracts on continuous sucrose gradients reveals a complex profile reflecting the AChE polymorphism (Fig. 1). We identify five major forms of AChE: 3.5, 6, 11, 14, and 18 S.

After treatment of the muscle extracts by collagenase, at 20°C, there is no change in total AChE activity. The collagenase treatment at 20°C provokes an increase of the sedimentation coefficients of the two heavy forms, from 14 and 18 S to 16.5 and 20.5 S, respectively, (Fig. 2). Incubation of samples without collagenase at 20°C, or heat-inactivated collagenase (80°C for 10 min) does not lead to any change in the sedimentation profiles.

After dialysis of the standard medium muscle extract against a low ionic strength medium (0.001 M EGTA, 0.01 M Tris-HCl, pH 7.2) 3 h, at 4°C, the sedimentation in a low

Sedimentation analysis of AChE from control MEP-r region and BL. (A) Control muscle. (B) BL 15 d after lesion. Extraction was in standard (detergent-high salt) medium in the presence of protease inhibitors. The two curves are quantitatively directly comparable, although sedimentation distances were slightly higher in experiment B.

AChE Forms in BL Preparation. The procedure of Sanes et al. (28) gives a biological preparation of myofiber ghosts, which still contains the BL of the original myofiber in the MEP-r regions. An electron microscope study (Fig. 3; see also Fig. 6) shows, 15 d after surgery, that empty BL co-exists with surrounding degenerating Schwann cell processes, fibroblasts, nerve terminal debris, and collagen fibrils. Sometimes, the BL contains small mononucleated cells, probably macrophages and muscle satellite cells (Fig. 6a). Small fragments of plasmic membranes are occasionally seen attached to the inner surface of the BL. Most of the basal lamina does not show any important folded part except in a restricted region in which BL infolding (Fig. 3g) is of the size and periodicity of the junctional folds of postsynaptic membrane in intact muscle (Fig. 3c), as already observed in an independent study by Sanes and Chiu (27).

The quantitative analysis of AcChR estimated by $^{125}$I-$\alpha$-}

Figure 4. Sedimentation analysis of AChE from control MEP-r region and BL. (A) Control muscle. (B) BL 15 d after lesion. Extraction was in standard (detergent-high salt) medium in the presence of protease inhibitors. The two curves are quantitatively directly comparable, although sedimentation distances were slightly higher in experiment B.
Bgtx binding (Table I) shows that the total α-Bgtx binding in the BL was ~3% of that found in the normal MEP-r region.

AChE was extracted from control MEP-r regions or experimental BL bridges in a one-step standard medium procedure. The presence or the absence of protease inhibitors did not change the relative proportion of AChE forms. Fig. 4 shows that all AChE forms are found in the BL, with the same S values as in normal muscle. Table II shows that there is no drastic change in their relative proportion, except for a significant decrease of the 3.5 S (Student's t-test, *P* < 0.01) and 18 S (*P* < 0.05) forms. Table III gives the total and specific activities of the main molecular forms of AChE in the MEP-r regions of the muscle and in the BL preparation. A rather important proportion of activity, ~20–50% relative to that of the intact MEP-r regions, remains in the BL. An important decrease of protein content (by a factor of 5) of the BL preparation is responsible for a significant increase (*P* < 0.01) of specific AChE activity of each form, except for the 3.5 S form, which remains at about the same level.

After irreversible inhibition in vivo by MPT of all preexisting enzyme, AChE recovery was compared in MEP-r and BL.

Table I. Distribution of α-Bgtx Binding Sites (AChR) in Total Extracts of Cutaneus Pectoris MEP-r Region and of BL Preparations

|                      | Total α-Bgtx* | Specific binding per mg protein |

asymmetric forms (14 and 18 S) represented ~5% only of the activity recovered after 216 h.

**Purification of BL Sheaths: Pure BL Sheaths Still Contain Asymmetric AChE Forms**

We performed a mild extraction of the BL bridges by simple incubation in the detergent medium. AChE staining (15) rather similar to that observed in the BL bridges (22) is still present after this detergent treatment (data not shown). This mild extraction eliminates completely mononucleated cells and cellular debris that contaminates the original BL bridges (Fig. 6). Detailed ultrastructural studies demonstrate that there is only one remaining organized structure, the muscle BL (Fig. 7). However, some ultrastructural aspects of the purified BLs are modified. The dense, centrally located part of the BL has disappeared. The AChR, which remained in the crude BL preparation, is mostly solubilized by the mild detergent treatment: ~91% of the total α-BgTx binding capacity of the BL bridges (and 85% of that of the MEP-r regions) is recovered in the exudate.

AChE is only partially released from the bridges by the detergent exposure. The loss of individual forms in the exudates ranges between 30 and 50% of their original content in these tissues (Table IV). All forms are still present in the pure BL sheaths, as shown in Fig. 8. We found that the total amounts of asymmetric and globular forms that remain in both MEP-r regions and pure BL bridges are very similar (50 to 70%, Table IV).

**Discussion**

McMahan and associates (20) have shown that most synaptic AChE in frog muscle is associated with muscle BL. An important feature of BL AChE emerges from our work: all major globular and asymmetric AChE forms are present in the external layers of the frog muscle MEP-r regions. The BL preparation is obtained in vivo after muscle damage, leaving a bridge of BL ghosts that contains the old sites of the MEP.

![Figure 6. Effect of a mild exposure to detergent on the BL bridges: purification of BL. Low power micrograph (a) before and (b) after treatment. (M, macrophage. Arrowhead, collagen fibrils. * Micromoles hydrolyzed AchCh per minute per MEP-r or BL ± SEM of three independent experiments.

* Percentage of total activity recovered for each AChE peak in the mild detergent treatment compared with its total AChE activity, determined by three successive extractions: mild exposure to detergent, detergent extraction, and high salt extraction of the resulting pellet.
Thus, the BL preparation is enriched in synaptic BL, although the enrichment is not very important. In intact cutaneus pectoris muscle we estimated that the synaptic area corresponds to 0.1% of the total myofiber surface, as compared with 1 or 2% in the experimental bridge. We are thus not dealing with synaptic BL only but with a mixture of synaptic and extrasynaptic elements. The presence of asymmetric forms of AChE in muscle BL is directly demonstrated in this report. Until recently, only indirect evidence for a BL location was available: (a) the collagenous nature of the tail part of AChE and its aggregation properties (3) suggested a possible attachment to acidic components such as those found in BL; (b) asymmetric AChE is generally found in an external location, as shown with the use of reversible and irreversible, permeant or nonpermeant inhibitors (5, 12, 17, 18, 34). Globular AChE forms are also found in the frog BL preparation in contrast to mouse muscle and almost in the same proportions as in normal, intact muscle. Both globular and asymmetric forms were not recovered in significant amounts after irreversible inactivation by an organophosphorus compound, MPT. Thus, the AChE forms present in frog BL are not synthesized by contaminating or invasive cells or do not have an extraterritorial origin. Globular forms of AChE are found in BL ghosts later, 24 d after surgery and 15 d after the muscle is damaged. The same proportions of these forms have been found earlier, 7 d after surgery. Thus, the globular forms are probably not degradation products of the original asymmetric forms present in the BL of intact muscle, unless transitory proteolysis is activated during the first week after damage. Recent results from McMahan’s group (1) differ from ours: only a 4.5 S globular form of AChE was found in the BL preparation obtained 30 d after damaging of the muscles of Rana pipiens frogs. The use of frogs of different origin (R. pipiens and R. temporaria) or even simply different extraction conditions may explain these differences.

As already pointed out by Anglister and McMahan (1), the presence of globular forms in the BL preparation suggests that AChE does not need to have a tail structure to remain associated with the BL. Moreover, the presence of globular forms of AChE in intact BL raises the possibility of a functional role for these forms at a junctional as well as at an extrajunctional location. Such a role has already been suggested at the nerve-muscle junction of chicken slow muscle.
which lacks asymmetric 20 S AChE (2).

Our results concerning the presence of all forms of AChE in BL raise the question as to how these forms are inserted into the BL structure, the physicochemical nature of their association with other BL molecules (collagen type IV, fibronectin, laminin, polyanionic components), and their precise physiological role at these extracellular synaptic locations.

We are grateful to Dr. S. Schraub, Mr. P. Courvoisier, and Mrs. J. Fournier (Service de Radiothérapie, Centre Hospitalier Régional, Besançon, France) for their assistance in x-irradiation.
