Edited by Daniel Falush, University of Bath, Bath, United Kingdom, and accepted by Editorial Board Member W. F. Doolittle April 30, 2021 (received for review July 22, 2020)

The gastric bacterium Helicobacter pylori shares a coevolutionary history with humans that predates the out-of-Africa diaspora, and the geographical specificities of H. pylori populations reflect multiple well-known human migrations. We extensively sampled H. pylori from 16 ethnically diverse human populations across Siberia to help resolve whether ancient northern Eurasian populations persisted at high latitudes through the last glacial maximum and the relationships between present-day Siberians and Native Americans. A total of 556 strains were cultivated and genotyped by multilocus sequence typing, and 54 representative draft genomes were sequenced. The genetic diversity across Eurasia and the Americas was structured into three populations: hpAsia2, hpEastAsia, and hpNorthAsia. hpNorthAsia is closely related to the subpopulation hs IndigenousAmericans from Native Americans. Siberian bacteria were structured into five other subpopulations, two of which evolved through a divergence from hpAsia2 and hpNorthAsia, while three originated though Holocene admixture. The presence of both anciently diverged and recently admixed strains across Siberia support both Pleistocene persistence and Holocene recolonization. We also show that hs IndigenousAmericans is endemic in human populations across northern Eurasia. The evolutionary history of hs IndigenousAmericans was reconstructed using approximate Bayesian computation, which showed that it colonized the New World in a single migration event associated with a severe demographic bottleneck followed by low levels of recent admixture across the Bering Strait.

Helicobacter pylori | Siberia | Americas | colonization | demographic model

The gram-negative gastric bacterium Helicobacter pylori has shared an intimate coevolutionary relationship with humans for the last 100,000 y and possibly longer (1, 2). The greatest genetic diversity in both humans and H. pylori is found in Africa, the ancestral homeland of both species (3). After leaving Africa, H. pylori continued to differentiate in tandem with humans. Unlike its host, the bacterium evolved into multiple distinct geographic populations because it has high mutation and recombination rates, shorter generation times, and lower effective population sizes (4). Human populations expanding along the southern Asia coastal route carried the H. pylori precursors of hp Sahul, a divergent, monophyletic population that continues to infect New Guinean Highlanders and Aboriginal Australians (5). The western and central parts of Paeleolithic Eurasia were dominated by hpAsia2, which has differentiated into hpIndia and hpLadakh (6, 7).

A Eurasian West–East divide in H. pylori is reflected by the divergence of hpEastAsia, an ancestral East Asian population, into subpopulations hpEAsia (Southeast and East Asians), hs IndigenousAmericas (formerly known as hpAmerind, native North and South Americans), and hpMaori (Austronesian speakers). However, H. pylori’s presence, diversity, and structure in northern Eurasia are still unknown. This vast region, hereafter Siberia, extends from the Ural Mountains in the west to the Pacific Ocean in the east and the Kazakh and Mongolian Steppes in the south. Siberia is inhabited by at least 41 ethnic minorities who often live in small communities of low population densities with a total of <250,000 individuals (8). Notwithstanding often harsh environmental conditions, Siberians subsist through hunter-gathering and/or pastoralism (9), and the diversity of language families spoken in the region (Uralic, Yeniseian, Turkic, Tungusic, Mongolic, Gilyak, and Chukotko-Kamchatkan) hints at a complex history of migration and isolation.

The patterns of human diversity between these ethnic groups are also largely understood, and most genetic studies were based on traditional markers such as mitochondrial or Y chromosome DNA, whose effectiveness is compromised by relatively low mutation rates and incomplete lineage sorting (10–15). Recently, genomic studies of ancient human DNA have offered further insights, confirming that Siberia was the gateway for

Significance

The peopling of Siberia and the Americas is intriguing for archaeologists, linguists, and human geneticists, but despite significant recent developments, many details remain controversial. Here, we provide insights based on genetic diversity within Helicobacter pylori, a bacterium that infects 50% of all humans. H. pylori strains were collected from across eastern Eurasia and the Americas. Sequence analyses indicated that Siberia contains both anciently diverged and recently admixed bacteria, supporting both human persistence over the last glacial maximum and more recent human recolonization. We inferred a single migration across the Bering land bridge, accompanied by a dramatic reduction in effective population size, followed by bidirectional Holocene gene flow between Asia and the Americas.

human migrations into northern America (16, 17) as well as into western Eurasia (18).

Two important questions remain unanswered. Firstly, although anatomically modern human hunter-gatherers first appeared in Siberia 45,000 y ago (kya) in the Upper Paleolithic (16), their continued presence in the region throughout the last glacial maximum (LGM, 26.5 to 19 kya) is controversial. One argument suggests that ancient northern Eurasian [ANE (19)] metapopulations in Siberia had already developed adaptive mechanisms that allowed them to persist throughout the LGM, at least in sheltered locations with favorable environments (20). The presence of genetically similar human remains in central Siberia at 24 kya (Ma’ta boy, MA1) and 17 kya (AG2) (17) also hints that the region may have been continuously inhabited by ANEs during the LGM. Conversely, other scientists propose that the LGM paleoclimate resulted in the complete depopulation of central Siberia, driving humans into refugia to the south where they persisted for thousands of years before repopulating northern Siberia during the Holocene (9, 21, 22). Secondly, the peopling of the Americas by anatomically modern humans has long attracted scientific attention. Recent genomic evidence suggests that a single genetically diverse human population migrated across the Bering land bridge into the Americas, followed by subsequent post-LGM gene flow (23, 24). However, the dates of colonization by these migrants, the size of their founder population, and their relationships to other human groups remain unclear.

To help answer these and other questions about human movements through Eurasia and the Americas, we undertook large-scale sampling of H. pylori from ethnically diverse aboriginal human populations across Siberia and Mongolia. Genotyping and sequence data were combined with a large reference database of Asian strains to provide an overview of the population structure of their genetic diversity and to infer the demographic and evolutionary histories of the peoples of Siberia and the Americas.

Results

From 2004 to 2006, we sampled H. pylori from 16 ethnic and multiple traditional language groups (SI Appendix, Table S1 and Fig. S1) during visits by an experienced gastroenterologist to 18 geographic locations groups in Russia and Mongolia spanning northwestern, central, northern, and eastern Siberia and Berin- gia. The language families sampled included Uralic, Turkic, Mongolic, Tungusic, and Chukotko-Kamchatskan as well as two isolate languages spoken by the Ket of the Yenisei Valley and the Nivkh of Sakhalin Island. A total of 1,175 gastroendoscopic biopsies were taken from the antrum and/or corpus of the stomachs of volunteers without mishaps and with informed consent and frozen immediately in liquid nitrogen before shipping to Moscow. A total of 556 independent strains of H. pylori were cultivated from the frozen biopsies and DNA was extracted. Seven MLST (multilocus sequence typing) housekeeping genes spanning 3,406 nucleotide positions were sequenced by classical Sanger sequencing as described (4). We also extended these studies with higher resolution genomic short-read sequencing for a subset of 40 representative H. pylori strains from around the globe as well as 54 of the indigenous H. pylori strains cultured from 14 ethnicities in Siberia and the New World (Dataset S1). The short reads were assembled into draft genomic sequences in EnteroBase (25) and used to assess population structure at the genomic level.

Russians colonized Siberia centuries ago, and H. pylori from Russians usually belong to the hpEurope population (3), which evolved through Neolithic admixture (26). We were therefore not surprised that 160 of the Siberian isolates belonged to hpEurope and ignored them here because of numerous prior studies on such isolates from Europe (2–5, 27). Instead, we focus on the remaining 396 bacterial strains which were assigned to Asian populations. These Siberian MLST genotypes were combined with previously described H. pylori genotypes from other global sources (36 human populations in Asia, Oceania, and the Americas (4–7, 27–32); Dataset S2 and SI Appendix, Fig. S1) for a total of 1,002 genotypes and 1,952 polymorphic sites, which were used to elucidate the evolutionary history of H. pylori in Siberia.

The Structure of H. pylori Variation in Eastern Eurasia and the Americas. We analyzed the genetic structure of our H. pylori MLST data set using model-free discriminant analysis of principle components (DAPC) (33) as well as the linkage model in STRUCTURE (34). Both approaches identified 10 distinct subpopulations (Fig. 1 and Table 1 and SI Appendix, Figs. S2 and S3), five of which (hspAltai, hspUral, hspSiberia1, hspSiberia2, and hspKet: Dataset S2) are first described here. hspIndiand hspLadakh from South and Southeast Asia are previously described subgroups of hpAsia2. Our DAPC results show that hspUral from Uralic-speaking Khants and Nenets

![Fig. 1. MLST genetic variation of H. pylori structured into 10 subpopulations of populations across Asia and the Americas.](https://doi.org/10.1073/pnas.2015523118)
of northwestern Siberia is a third, slightly divergent hpAsia2 subpopulation (Fig. 1B and SI Appendix, Figs. S4 and S5). hpEAsia and hpMaori (Table 1) are found predominantly in East Asia, island Southeast Asia, and the Pacific and belong to the hpEastAsia population. Previous analyses suggested that the hpIndigenousAmericas subpopulation isolated from Native Americans also belonged to hpEastAsia (4, 5). The added resolution afforded by our extensive sampling reveals this conclusion to be incorrect. We now find that hpIndigenousAmericas also included 103 other strains found in Beringia (Chukchi, Koryak, Even) along the East Siberian coast as far south as Sakhalin Island and the Lower Amur Valley and was isolated from Uralic (Khart and Nenet) and Yenisein (Ket) speakers in northwestern Siberia (Table 1). hpIndigenousAmericas was notably absent in central Siberia (Fig. 1A) except for four isolates from Evenk and one from Mongolia. The combined hpIndigenousAmericas subpopulation from Asia and the Americas is also clearly not a subgroup of hpEastAsia (Fig. 1B). Instead, hpIndigenousAmericas is most closely related to a new subpopulation, which we designated as hpAltai. hpAltai was restricted to central Siberia, where it was found with high frequencies among Turkic (Tuvan, Tubalar, Yakut) and Mongolic (Buryat, Mongolian) speakers and at lower frequencies in Evenk and Orok Tungusic groups (Fig. 1B and Table 1). hpIndigenousAmericas and hpAltai form a population that we designate hpNorthAsia, which accounted for 44% of Siberian H. pylori. The majority of our Siberian genotypes (52%) clustered distinctly from all of these H. pylori populations and subpopulations (Fig. 1B). They formed three somewhat overlapping subpopulations (hpSiberia1, hpSiberia2, and hpKet) in the center of the triangular DAPC cluster delineated by hpEastAsia, hpNorthAsia, and hpAsia2 (Fig. 1B). hpSiberia1 was geographically widespread and was isolated from all sampled ethnicities across northern Eurasia (Fig. 1A and Table 1). hpSiberia2 was also widely distributed across Siberia, albeit at lower frequencies and from fewer ethnicities than hpSiberia1. The third new subpopulation, hpKet, was exclusively found among ethnic Kets in central Siberia (Fig. 1B and SI Appendix, Fig. S4).

We also investigated the relationship between these subpopulations on a subset of 94 complete genomes (of which 54 originated in Siberia). Maximum likelihood trees were generated from genomic single-nucleotide polymorphisms after removing recombinant regions that were detected with Gubbins (35). A total of 40 genomes from previously defined subpopulations formed subpopulation-specific monophyletic clades, except for a partial overlap of hpIndia and hpLadakh (SI Appendix, Fig. S6A), which also overlap somewhat in geographical location and in DAPC space (Fig. 1B). In a larger tree containing 54 additional Siberian genomes, hpUral and hpAltai also formed monophyletic clades (SI Appendix, Fig. S6B and Table 1). As expected, hpUral was closely associated with hpLadakh and hpIndia, while hpAltai was nested within hpIndigenousAmericas. Both trees also showed that hpNorthAsia genotypes diverged from a common ancestor and were not nested within hpEastAsia.

In contrast to these monophyletic clades, 19 hpSiberia1, hpSiberia2, and hpKet genomes formed long branches, did not cluster uniformly according to their subpopulation designations, and were intermingled to some extent with hpNorthAsia, hpEastAsia, and hpAsia2 genomes (SI Appendix, Fig. S6B). A total of 15 of those genomes had <95% bootstrap support. Together with the intermediate and overlapping positions in the DAPC plot described above, these results indicate an absence of discrete or robust structure which might possibly result from extensive mixed ancestry.

We therefore investigated the sources of ancestry of all core genomes of Siberian strains with fineSTRUCTURE (36), which has previously been used to demonstrate shared ancestry among recombinant H. pylori genomes (26, 37). The coancestry matrix (Fig. 2) supported a distinct clustering of populations hpNorthAsia, hpEastAsia, and hpAsia2 and most of their subpopulations, consistent with the phylogenetic results described above (Table 1). However, the fineSTRUCTURE results were also partially inconsistent with the DAPC assignments to the subpopulations hpSiberia1 and hpSiberia2. A total of 15 genomes clustered together with hpEastAsia, but three clustered with

hspIndigenousAmericas and one with hspUral (horizontal arrows, Fig. 2). In contrast, the two hspKet genomes clustered discretely with hpNorthAsia strains from Uralic-speaking Nenets and Khants, indicating a closer affinity to this population and an independent origin from other Siberian strains. Importantly, the coancestry heat map showed that strains assigned to Siberian subpopulations (dashed boxes) shared considerable proportions of their ancestry (darker shading) with each other and, to a lesser extent, with other genomes from hpNorthAsia, hpEastAsia, hspLadakh, or hspIndia (Fig. 2). Quantifying these proportions of ancestry in Siberian strains, we found that the highest levels corresponded to hpNorthAsia, hpAsia2, and hpEastAsia (SI Appendix, Table S2). The combination of these results indicates that modern Siberian subpopulations have signals of admixture between multiple ancestral populations.

Evolutionary Origins of Siberian Subpopulations. We attempted to elucidate the evolutionary dynamics of H. pylori in Siberia assessing demographic simulations via approximate Bayesian computation [ABC (38); reviewed in ref. 39]. We defined sets of alternative demographic histories (“models”) that could potentially have generated the observed MLST sequence distributions. A coalescent simulator was then used to simulate DNA sequence evolution according to each of the predefined models. The simulated data were compared to the observed MLST sequences, and the model that retained the largest number of simulations at three threshold levels was chosen as best fit to the data. We also used this approach to model migration into the Americas and to date the occurrence of branch points and admixture events in the phylogenies.

We defined the model populations on the basis of the observed genetic structure above, independent of the geographic origins of samples. The models began with H. pylori’s well-established West–East divide (40), which is reflected by the split between hpAsia2 and the common ancestor of hpEastAsia and hpNorthAsia (2, 5). We inferred the origins of hspSiberia1 and hspSiberia2, the two most common Siberian populations, by simulating a range of tree-like and admixture-based demographic models (SI Appendix, Fig. S7 and Table S3). Models one to four are tree-like; they postulate that subpopulations diverged from an ancestral population exclusively by mutation and drift. Models five to seven hypothesize that a subpopulation evolved by hybridization between two ancestral populations. The coancestry matrix (Fig. 2) and proportions of shared ancestry (SI Appendix, Table S2) suggest hpAsia2, hpNorthAsia, and hpEastAsia as potential ancestral populations, excluding hspUral, whose members...
are unusually divergent (Fig. 1B and SI Appendix, Figs. S4 and S5) and share fewer ancestral motifs with hspIndia and hspLadakh. A visual examination of principal component analyses (PCA) (SI Appendix, Figs. S8 and S9) indicated that the seven models were able to generate the observed data. Logistic regression showed that model posterior probabilities were stable with increasing numbers of retained simulations (SI Appendix, Table S4), and the best models yielded median posterior mutation rates of similar magnitudes to previously estimated long-term rates (1, 41). Coalescent generations were converted to years using the calibration of 1 y per generation previously established from population divergence time estimates (2, 5) and mutation rates (1). The best fit models for hspSiberia1 and hspSiberia2 indicated that both originated through admixture rather than divergence. The best model for hspSiberia1 (model seven; Fig. 3A) inferred evolution through admixture between hpAsia2 and hpNorthAsia. hpAsia2 was also one of the admixture partners for hspSiberia2, but the other partner was hpEastAsia rather than hpNorthAsia (model six, Fig. 3B). The top models chose different admixture sources but yielded similar posterior estimates of their parameter values (SI Appendix, Figs. S10 and S11 and Table S5). The admixture events were relatively recent, ~2,630 (hspSiberia1; R^2 = 0.51) and 2,933 (hspSiberia2; R^2 = 0.52) y ago.

DAPC (Fig. 1B and SI Appendix, Fig. S4) and fineSTRUCTURE (Fig. 2) analyses suggested that hspKet might have arisen through admixture. The observation that hspKet was only resolved by DAPC at K > 9 suggested that admixture might have between preexisting admixed populations, such as hspSiberia1 or hspSiberia2, and older populations, such as hpEastAsia or hpNorthAsia. We therefore built the reconstructed demographics inferred for hspSiberia1 and hspSiberia2 into five new models to test the origins of hspKet (SI Appendix, Fig. S12 and Table S6). The best model for the evolution of hspKet was that of secondary admixture between hspSiberia2 and hpNorthAsia ~2,165 y ago (Fig. 3C and SI Appendix, Figs. S13 and S14 and Tables S4 and S7). Thus, these analyses indicate that admixture was involved in the evolution of hspSiberia1 and hspSiberia2 as well as hspKet and also provide explanations for their equivocal clustering in phylogenetic (SI Appendix, Fig. S6B) and fineSTRUCTURE analyses (Fig. 2).

We now turn to hspAltai. This subpopulation was assigned to hpNorthAsia as was hspIndigenousAmericas (Figs. 1B and 2 and SI Appendix, Fig. S6B). We therefore used our ABC framework to estimate the divergence time of hspAltai from hpNorthAsia at ~983 y ago (R^2 = 0.70; SI Appendix, Figs. S15 and S16 and Tables S4, S8, and S9).

Migration of \textit{H. pylori} from Siberia into the New World. We also used ABC comparisons between multiple models to reconstruct the evolutionary history of the hpNorthAsia subpopulation hspIndigenousAmericas as it migrated from Eurasia into the Americas, but the populations used for modeling were based on geographical populations rather than genetic clusters. We restricted these analyses to hspIndigenousAmericas because no other aboriginal \textit{H. pylori} subpopulation has been isolated from Native Americans. hspIndigenousAmericas genotypes were assigned to four spatial populations based on their geographic distributions across Siberia and the Americas. These were designated NS (northern Siberia; ethnic groupings: Khanty, Nenet, Tuvan, and Even); ES (eastern Siberia; Nivkh, Orok, and Nanai; n = 20); KC (Kamchatka-Chukotka; Chukchi, Koryak, and Even; n = 35), and AM (Americas; Eskimo, Athabaskan, Venezuelan, Huitoto, and Peruvian; n = 19) (Fig. 4A). The geographic boundaries of the four regions correspond to geographical areas with elevated frequencies of K1 to K3, three genetic sub-subpopulations that were discerned by a DAPC analysis of hspIndigenousAmericas strains (SI Appendix, Fig. S17 and Fig. 4B). hspIndigenousAmericas from the Ket ethnic group, which comprised the K4 DAPC cluster, were excluded because they might confound the analyses due to high genetic variance (Fig. 4B) and their demonstrated history of isolation and admixture (Fig. 3C). We developed eight demographic models that potentially reconstruct the history of hspIndigenousAmericas and its colonization of the American continent, using a representative population (Hong Kong) of hpEastAsia (EA) as an outgroup (SI Appendix, Fig. S18 and Table S10). Models one to four depicted

\begin{figure}
\centering
\includegraphics[width=\textwidth]{fig3.png}
\caption{Best supported models for the evolution of newly discovered \textit{H. pylori} subpopulations hspSiberia1 (A) and hspSiberia2 (B) and hspKet (C) using ABC. (A–C, Top) Sampled locations containing either source or admixed populations, the proposed migration routes of both source populations (thick arrows), and the recent colonization routes once admixture occurred (thin arrows). The transparent pie slices therefore correspond to populations that were not involved in the depicted scenario. hspSiberia1 originated through admixture between hpAsia2 and hpNorthAsia, hspSiberia2 derived via admixture between hpAsia2 and hpEastAsia, and hspKet evolved though admixture between hpNorthAsia and hspSiberia2. The median posterior estimates for admixture times (Tadm) are given for each analysis.}
\end{figure}
simple tree-like scenarios. Models one, three, and four were based on the underlying ingroup topology deduced from DAPC, with the initial branching of northern Siberia followed by ES, KC, and finally AM [base topology (ES(NS(ES(KC,AM))))]. Model two was based on an alternative topology, namely an early split of Native American H. pylori from Siberian bacteria. Models three and four tested whether gene flow between KC and AM occurred early (model three) or late (model four) in order to distinguish whether migrations to America preceded or succeeded the flooding of Beringia (42). Model five explicitly tested the existence of gene flow between H. pylori from ANEs (represented by NS) and Native Americans as postulated by Raghavan et al. (17). American H. pylori may also have undergone a reduction in effective population size during the flooding of Beringia; this bottleneck was simulated in models six through eight, with American H. pylori splitting from the ancestors of ES and KC. Model six excludes gene flow between Siberia and AM after the bottleneck, whereas model seven includes bidirectional gene flow across the Bering Strait in accordance with Reich et al. (23). Models six and seven both envision gene flow from NS to ES, whereas model eight envisions additional bidirectional gene flow between ES and KC in order to account for similarities in H. pylori sequences from both regions.

PCA confirmed that our models were able to reproduce the observed data (SI Appendix, Fig. S19), while regression analyses (SI Appendix, Table S4) supported model seven for the evolutionary history of HspIndigenousAmericas (Fig. 4C). Thus, H. pylori’s colonization of the Americas comprised the migration of a population that was ancestral to those presently inhabiting the eastern and northeastern reaches of Siberia, across Beringia and into North America ~12 kya (95% highest posterior density [HPD] 3,105 to 22,512 y, Fig. 4C). The effective population size of the founding H. pylori was very small (ancestral effective population size = 167). This founding population subsequently expanded considerably after migrating from Siberia to a current effective population size of 54,255 (Fig. 4C and SI Appendix, Fig. S20 and Table S11).

Discussion

The Structure of hpAsia2 in the Paleolithic. hpAsia2 was one of the first H. pylori populations to evolve outside Africa, and these bacteria infected a 5,300-y-old frozen mummy in the Italian Alps (26) and may even have been dominant in western and central Eurasia during the Paleolithic. Today, hpEurope H. pylori predominate in Europe and the surrounding areas of western Asia. However, hpAsia2 may have accompanied the first modern human hunter-gatherers into the region over 40 kya (43). Pure hpAsia2 occurs at low frequencies among Finnish and Estonian Uralic speakers, on the fringes of the range of hpEurope, and is found at higher frequencies in Central and Southeast Asia (3, 7, 44). The data presented here show that Uralic speakers in northwestern Siberia of the Khanty and Nenet ethnicities are found at higher frequencies in Central and Southeast Asia (3, 7, 44). The data presented here show that Uralic speakers in northwestern Siberia of the Khanty and Nenet ethnicities are infected by hspUral, a novel subpopulation of hpAsia2. The existence of hspUral indicates that hpAsia2 may once have been highly structured across its erstwhile Eurasian range. It also raises the possibility that hspUral might represent a microbial marker for future investigations of the westward expansion of Uralic language speakers from Siberia into northern Europe.

Equally intriguing is the propensity of hpAsia2 to form recombinant populations upon secondary contact with other H. pylori populations. In 2003, Falush et al. (4) established that hpEurope was derived from admixture between ancestral hpAsia2 and hpNEAfrica populations, the latter of which left Africa during a recent out-of-Africa migration (2). As shown here, hpAsia2 was also involved on its eastern frontiers in two further admixture events with hpNorthAsia and hpEastAsia, yielding the recombinant subpopulations hspSiberia1 and hspSiberia2, respectively. Indeed, all known recombinant H. pylori populations worldwide include hpAsia2 as one of the parent populations. Yet, other secondary contacts between H. pylori populations not involving hpAsia2 did not prevent the continued coexistence of discrete populations in Africa (hpAfrica1 and hpNEAfrica) (45) and the New World (hspIndigenousAmericas and hpEurope) (3). These contrasting historical developments may reflect the especially high fitness of hpAsia2 genes that drive the expansion of their recombinant descendants. Alternatively, the expansion of recombinant populations may have been driven by repeated
Paleolithic and Holocene introductions of hpAsiа2 into geographic areas containing other populations.

Our data also indicate additional admixture events for the evolution of hspKет, which currently consists of 11 isolates from Solumai. Other biopsies from Solumai yielded 11 H. pylori strains assigned to hpIndigenousAmericas and three to hpSiberia1. Our ABC analyses indicated that the evolutionary origin of hspKет was through admixture between hpNorthAsia and hpSiberia2 (model one; Fig. 3C). However, hpSiberia1 is closely related to hpSiberia2, and also to their parent populations, and we cannot definitely exclude alternative evolutionary scenarios because the four other models tested also yielded appreciable probabilities (SI Appendix, Table S4). Resolving this issue would require additional samples and higher resolution comparisons based on whole-genome sequences, which are not currently available. Due to these uncertainties, we ignored all H. pylori isolated from Kets for our reconstructions of the migrations to the Americas. Comparisons of additional samples and whole-genome sequences might elucidate additional migration events in Eurasia and to the Americas that involved hpSiberia1 and/or hpSiberia2 and their descendants.

**The Peopling of Siberia.** Our reconstruction of the evolutionary history of four novel H. pylori subpopulations brings insights into past human movements in central Siberia. Three of these subpopulations (hpSiberia1, hpSiberia2, and hspKet) arose via admixture relatively recently, likely during the Holocene. We postulate that each of these evolved from recent secondary contact of populations previously isolated in LGM refugia across central or southern Siberia. This concept is also in accord with the hypothesis of a recent Holocene repopulation of northern Siberia (9, 21, 22). hpAltai arose by genetic drift from a common ancestor with hpNorthAsia; it is also likely to have differentiated in isolation near its current sources in central Siberia. We dated the split that led to hpAltai as 199 to 2,329 y ago, and its current proliferation among Turkic- and Mongolic-speaking Siberians suggests that it may have spread through the region together with recent Turkic (sixth to 16th centuries) and Mongolic (13th century) migrations (46).

The presence of other nonadmixed populations of hpIndigenousAmericas strains among northern Siberians (e.g., Khants, Nenets, and Evenks) and hspIndigenousAmericas strains among Khants and Nenets is less compatible with expansion from refugia in southern areas. Instead, these strains may have infected ANE populations. Comparison of additional samples and whole-genome sequences might elucidate additional migration events in Eurasia and to the Americas that involved hpSiberia1 and/or hpSiberia2 and their descendants.

**Peopling of the Americas.** One of the most exciting findings presented here is the existence in Siberia of hpNorthAsia, which encompasses the hpAltai and hpIndigenousAmericas subpopulations (Fig. 1). hpAltai is concentrated in central Siberia, but hpIndigenousAmericas exists throughout Siberia from west to east and throughout the Americas from north to south. Our earlier work demonstrated that hpIndigenousAmericas (at that time, hpAmericand) probably accompanied early American settlers over the Bering Strait (4), possibly even during their initial colonization of the Americas which began over 13 kya (48–50). Our understanding of the detailed Siberian genetic history that resulted in these intercontinental human migrations has been somewhat limited until recently due to a low resolution of traditional methods of human genetics and the lack of data (10–15). Recent developments have found that the human population of Beringia already contained the main East Asian and west Eurasian ancestral components common to all Native American populations before migration into North America (17, 24). The genomic distinctiveness of present-day Eskimo, Inuit, and Surui populations has been attributed to more recent Holocene bouts of gene flow across the Bering Strait (24, 51–53). The identification of hpIndigenousAmericas H. pylori and its subpopulations throughout Siberia provides additional context to help reconstruct those early migrations and their sources. Our data show Siberian substructure within hpIndigenousAmericas, with discrete sub-populations in the East (K2) and West (K3), which overlap in central Siberia (Fig. 4). A total of 18 H. pylori from the Americas belonged to the K1 subpopulation, as did 10 other isolates from Koryak, Chukchi, and Even ethnicities from Kamchatka and Anadyr in West Siberian Beringia. The presence of K1 hpIndigenousAmericas on both sides of the Bering Strait may reflect the ongoing interactions across the Strait between the inhabitants of the coasts of both continents (54, 55). However, the discrete geographic distributions between the other sub-populations of hpIndigenousAmericas over the entire extent of Siberia (Fig. 4) must reflect ancient patterns of isolation and supports the hypothesis of a single Pleistocene human migration into North America (23, 24).

These observations justify the use of ABC models to reconstruct H. pylori's colonization of the Americas. We inferred that American H. pylori populations branched from Eurasian hpIndigenousAmericas prior to the diversification of East Siberian and Chukotko-Kamchatkan populations, and we dated the median time for this event to ~12 kya, albeit with wide 95% HPDs (9). One migration across the Bering land bridge that colonized both North and South America is not readily conceivable more recently than ~11.500 kya, after the inundation of the Bering Strait (42). Although it is still debated whether Na-Dene–speaking Athabascans represent an additional source of ancestry from East Asia (23, 56), our analysis indicates that four Canadian Athabascan strains share common ancestry with the rest of American H. pylori and is in line with a hypothesis that the distinctiveness of the Na-Dene speakers evolved through an early divergence from other Native American groups shortly after the colonization of the New World followed by genetic drift (24, 57). However, our best fit model detected low levels of Holocene gene flow into AM from KC (Fig. 4C and SI Appendix, Table S11), potentially reflecting recent human migrations of Saqqaq paleo-Eskimos (52). We also detected migration in the opposite direction, which could represent back migration from the New World into northeastern Asia as previously described (23). Possibly stronger signals of American immigration from Eskimo and other sources might be obtained if additional H. pylori populations were sampled from northern Canada and Greenland.

hpIndigenousAmericas suffered a very severe demographic bottleneck during the initial stage of its colonization of North America, comprising no more than 10 to 854 effective bactera. However, our models cannot distinguish whether this bottleneck occurred during the migration from Siberia into Beringia and/or from isolation and genetic drift after crossing the Bering Strait. Our analyses estimate an increase in population size about 7 kya (95% HPD 680 to 16,849 y), but we consider the upper limit to be 12,500 y, when the recession of Cordilleran (west) and Laurentian (east) ice sheets created a corridor for human migration (58, 59). Alternatively, the earliest North American settlers would have to have migrated south along a coastal route (49) or by boats (60).

These population analyses and dating calculations are in accord with most archaeological estimates and support the hypothesis that North and South Americans are derived from a single pre-Holocene human migration of evolutionary ancient northern Eurasians into the Americas (23, 24). They also provide a bacterial perspective on the even earlier spread of anatomically modern humans throughout northern Eurasia.
Materials and Methods

H. pylori strains were cultured from gastric biopsies, which were de-identified after being collected endoscopically from volunteers with in-formed consent at 18 government hospitals or clinics in Russia and Mon-golia. This study was approved by the Charité ethics committee (Ethics certificate EA1/071/07). The details of the sampling procedure, populations, and fragment and genome sequencing are given in SI Appendix. MLST se-quences, primer combinations, and PCR conditions are available at https:// pubmlst.org/helicobacter. We also created an Enterobase (25) Helicobacter database (https://enterobase.warwick.ac.uk) that automatically assembles and annotates Helicobacter draft genome sequences from illumina short-read sequences, which are uploaded by Enterobase users or published in short-read archives. The Helicobacter Enterobase includes seven-gene MLST data and genomic sequences from the M.A. collection (1,871 seven-gene assembly clones and 226 single genomes). The details of the sampling procedure, populations, and fragment and genome sequencing are given in SI Appendix. Preliminary analyses were performed with 79 strains which belonged to both datasets (SI Appendix, Fig. S21 and Table S12). These were largely consistent but showed some discrepancies with isolates from North Asia. Therefore we reconstructed a reconstructed maximum likelihood phylogenetic trees using the best sub-stitution model for our dataset (K8P + ASC + R5) in IQ-TREE (62), with branch support determined by 1,000 ultraparameter replicates (63). To further investigate the ancestry of Siberian genomes, we employed ChromoPainter version 2 and fineSTRUCTURE version 4 (36). Full details are provided in SI Appendix.

We used the ABC framework (38) to model both the evolutionary origins of the new subpopulations hspSiberia1, hspSiberia2, hspKet, and hspAltaï as well as to reconstruct and date the migration of H. pylori into the Americas. All modeling details are provided in SI Appendix.

Data Availability. DNA sequence data have been deposited in Enterobase (http://enterobase.warwick.ac.uk/species/helicobacter/search_strains?query=workspace%3A49960 and http://enterobase.warwick.ac.uk/a/49884).

ACKNOWLEDGMENTS. We thank Kuvat Momynalyiev and Vera Cheslyeva for storing H. pylori biotypes, bacterial culture, and isolation. We thank Stefanie Bernhöft and Christiana Stamter for technical assistance with PCR and sequencing. We thank Kaia Thorell for assistance with the genome alignment and Andrinajoro Rakatoarivo for bioinformatic support. This work was supported by a grant from the Max-Planck Society and an Investigator in Science Award to M.A. (Grant No. 202729) from the Wellcome Trust.
