Comparative cervical profiles of adult and under-18 front-row rugby players: implications for playing policy

D F Hamilton,1 D Gatherer,2 J Robson,3 N Graham,3 N Rennie,3 J G B MacLean,4 A H R W Simpson1

ABSTRACT

Objective: To compare the cervical isometric strength, fatigue endurance and range of motion of adult and under-18 age-grade front-row rugby players to inform the development of a safe age group policy with particular reference to scrumming.

Design: Cross-sectional cohort study.

Setting: ‘Field testing’ at Murrayfield stadium.

Participants: 30 high-performance under-18 players and 22 adult front-row rugby players.

Outcome measures: Isometric neck strength, height, weight and grip strength.

Results: Youth players demonstrated the same height and grip strength as the adult players; however, the adults were significantly heavier and demonstrated substantially greater isometric strength (p<0.001). Only two of the ‘elite’ younger players could match the adult mean cervical isometric strength value. In contrast to school age players in general, grip strength was poorly associated with neck strength (r=0.2) in front-row players; instead, player weight (r=0.4) and the number of years’ experience of playing in the front row (r=0.5) were the only relevant factors in multivariate modelling of cervical strength (R²=0.3).

Conclusions: Extreme forces are generated between opposing front rows in the scrum and avoidance of mismatch is important if the risk of injury is to be minimised. Although elite youth front-row rugby players demonstrate the same peripheral strength as their adult counterparts on grip testing, the adults demonstrate significantly greater cervical strength. If older youths and adults are to play together, such findings have to be noted in the development of age group policies with particular reference to the scrum.

INTRODUCTION

Rugby Union (henceforth Rugby) is the world’s most popular sport, or more appropriately collision sport, and carries an injury risk four times greater than semicontact sports such as football/soccer.1 The scrum is an iconic and fundamental part of the game, where two ‘forward packs’ compete for the ball to restart the game following a minor infringement. It is a test of strength and technique where the cervical spine of the opposing front rows is subjected to huge compressive and shear forces of a sufficient magnitude to result in tissue injury and structural failure.2

Around 8% of all injuries in professional rugby are thought to result from the scrum.3 4 Injury events in amateur and youth rugby are thought to be similarly proportioned.5 Although 8% represents a comparatively small proportion of the injury burden, these injuries are likely to be of greater severity and involve the spine.6 Despite a typical match consisting of comparatively few scrums (compared to other contact events, such as tackles), around 40% of all rugby derived acute spinal cord injuries occur in the scrum.7 8 Scrum engagement occurs as the head and shoulders of the competing front rows make forceful contact. The force generated in the scrum engagement is thought to be a particular risk factor for injury, through high compressive and shear loads or hyperflexion of the cervical spine.7 9 This risk has been somewhat mitigated in recent years by the introduction of ‘controlled scrum engagement’ where the distance between opposing front rows has been standardised in an attempt to reduce acceleration and thus collision forces.10 11 Scrum collapse has also been identified as a leading cause of scrum-related injury.7 12 Premature micro trauma-induced degeneration of the cervical spine in front-row players13 and mismatches in size between front-row players7 14 have been suggested as potential factors for the over-representation of scrum-related injuries, though Brown et al note...
that coaching and technical factors have not been well explored in these analyses.

Body size and physical mismatch are considered (at least in part) to be associated with injury risk in schoolboy rugby.15 Some national governing bodies have introduced a weight category banding for youth rugby to address this concern in children who mature skeletally at differing rates. However, once players reach the age of 18, all participants are considered as adults and no such segregation takes place, and the banding rule no longer applies. Indeed, rugby is a sport that relies on differing physical attributes for the various playing positions. There are circumstances, though, where those yet to reach their 18th birthday may wish to play adult rugby, either through selection processes in the case of particularly gifted players, or through leaving school and joining a club playing in the adult leagues. The policy within Scottish Rugby (prior to the start of the 2013–2014 season) had been that only ‘exceptional’ 17-year-old players were eligible to play in the adult leagues; however, there was concern as to the suitability of this policy regarding the front row.

Although adequate cervical strength is relevant to all rugby players, the scrum exposes players’ cervical spines to potentially injurious forces that must be attenuated by controlled spinal motion through the cervical musculature, ligaments and intervertebral discs.16 Appropriate strength of the cervical musculature is thus particularly important for front-row players. The risk of scrum collapse (and, by extension, associated injuries) is increased if any of the six front-row players cannot maintain the muscular force required to complete the scrum. The overall compressive and shear forces generated in the scrum are only now being defined. These have been demonstrated to vary by playing level, with youth teams generating significantly lower forces than adult sides.2 However, the relationship between these overall scrum forces and the mechanisms by which the individual front-row players modulate them has not been explored. We have previously demonstrated large variation in the neck strength of school-aged rugby players;17 however, we are not aware of any report of data on maximal strength or fatigue endurance specific to the front-row forwards (either youth or adult). Characterisation of the strength profiles of the cervical spine of this specific group is thus warranted.

The aim of this study was to assess the cervical isometric strength and fatigue endurance of adult and senior school-aged rugby players to assess the ability of under-18 players to compete with adults in the front row of the scrum. A secondary objective was to assess the relationship between isometric strength and various physical parameters (such as age, weight and grip strength) previously shown to predict this.

METHODS

Cervical strength and endurance assessment

Isometric cervical muscle testing is well validated.18–20 We assessed maximal voluntary isometric cervical muscle strength with the GS Gatherer and GS Analysis Suite (Gatherer Systems Ltd, Aylesbury), a custom-built device based on a 300 kg load cell and bespoke software system. The test was performed employing a previously reported protocol17 21 where the head was placed in the neutral anatomic position and subjected to manual controlled incremental loading to positional failure (the point of head movement). Subject report of pain or neurological symptoms also stopped the test. Loading was applied and data were recorded at 20 Hz. Peak isometric force generated by the musculature was defined as the maximal load recorded during the test procedure. An average of three tests is reported, with a 60 s rest period enforced between assessments.

An assessment of cervical musculature fatigue endurance was made using the same test equipment. The player was required to exert an isometric extension load at 50% of their recorded mean peak extension force for as long as possible. The player sat in a neutral position with their arms by their side and head connected to the load cell. Players received a visual graphical feedback as to the target load applied via a computer monitor. This allowed for maintenance of a consistent load until failure. A single assessment was made of fatigue.

Anthropometric parameters

Additional measures were made of: height (Leicester Height Measure; SECA, UK), weight (medical grade mechanical flat scales; SECA, UK), grip strength (JAMAR hydraulic hand dynamometer; Sammons Preston, Illinois, USA) and cervical range of motion.
(Cervical Range of Motion Instrument, Performance Attainment Associates, Minnesota, USA). Three readings were obtained for each parameter and their average was derived and reported. Prior to the physical assessment, the player’s rugby playing history and detail of neck-specific training and injuries were determined using a self-reported questionnaire.

**Data analysis**

Data were analysed using Minitab (V.16). Data were checked for normality and are reported as means with SD or 95% CIs of the mean as a measure of dispersion. Independent sample t tests were used to assess differences in continuous variables between groups unless otherwise stated. Significance was accepted as p<0.05, incorporating the Benjamini-Hochberg correction for the testing of multiple hypotheses, to reduce the possibility of making a type I error in the interpretation of results.22 23

To assess the secondary research question as to predictive modelling of front-row player neck strength, all data were considered as a single cohort. Pearson correlation coefficients are reported for bivariate correlations. Stepwise regression modelling was performed to achieve the most predictive model for global neck strength (for which we use isometric extension) utilising the fewest variables. Predictive variables were selected if their bivariate significance was p<0.1 to accommodate the possibility of variables achieving statistical significance once the confounding influence of additional variables was controlled. A potential limitation of this approach is that the homogenised under-18 group may cause a clustering effect in the data. Separate analysis of the adult data demonstrates the same relationships as reported for the entire cohort lending credibility to the results presented. Further, all players assessed are eligible to play in the adult leagues and can thus be considered representative of a single cohort in the context of our secondary research question, to assess the influence of various physical variables (previously suggested to reflect the variation in cervical strength in a school-aged population) in the specific situation of the front-row player.

**RESULTS**

Large differences were observed between groups in terms of age and experience (years) playing as a front-row forward. There was no difference in height or grip strength between the groups, although the adults were significantly heavier. Cervical range of motion was similar in measures of extension and rotation, although the elite under-18 group had a greater range of cervical flexion and side flexion (table 1).

Differences were observed in isometric strength between groups in extension (figure 1 and table 2) and side flexion (table 2); the under-18 group was approximately 20% weaker than the adult group. A larger variation was seen in all parameters of adult neck strength data compared to the under-18 group. This may be due to the selection bias of elite players in the younger age group, which may have somewhat homogenised these data. Despite this potential positive skew in the under-18 data, only 2 of the 30 elite under-18 front-row players achieved the adult mean strength value (figure 1).

Only three of the under-18s achieved the adult mean isometric extension fatigue endurance (impulse, table 2); this difference between groups was significant at p<0.1, possibly reflecting the large variation in adult scores. The adults performed better in the fatigue assessment, holding significantly higher average loads for the same length of time as the younger players (table 2). Surprisingly, only a quarter of all players reported performing routine neck exercises, split evenly between groups (table 1).

**Predictive modelling**

Isometric neck strength was most associated with the experience of playing in the front row (r=0.5, p<0.001; figure 2), followed by weight (r=0.4, p=0.004) and player age (r=0.4, p=0.005). In contrast, grip strength correlated relatively poorly (r=0.2, p=0.09; figure 3). Cervical fatigue endurance was associated with peak isometric extension strength but correlated poorly (r=0.30, p=0.08). Player weight (r=0.6, p=0.007) was the factor most associated with fatigue; again, grip strength correlated poorly (r=0.1, p=0.6).

Stepwise regression determined the best predictive model for isometric strength to include the number of years’ experience playing in the front row and the players’ weight (table 3). The greatest single contributing variable was the experience of playing in the front row, which explained around 22% of the variation in isometric extension. The same variables also created the best predictive model of fatigue endurance, again explaining around a third of the variation in neck strength (R²=0.4).

**DISCUSSION**

This study demonstrates that even elite under-18 front-row rugby players, who have participated in a conditioning and strengthening programme, are able to generate significantly less cervical muscle force than adult players. This is relevant when determining the suitability of junior players to compete in the adult game, where significant forces are exerted through the cervical spine of the front-row forwards during the scrum. These forces must be modulated by the cervical musculature, and the reduced isometric strength and fatigue endurance ratings found in the under-18 players puts them at a significant disadvantage, with potentially injurious consequences. The under-18 players in this study were the top front-row players in Scotland, and this sample of players is most likely to be considered appropriate to play in the adult leagues as they may seem physically stronger and bigger. Based on this, it may then be
speculated that the difference in neck strength between
the general under-18 playing population and adults may
be even greater.

Little information is available as to the ‘neck strength’
of rugby players, either adult or school aged. We previ-
ously assessed the cervical isometric strength of Scottish
schoolchildren between the ages of 13 and 18 and
found a huge variation both within and between year
groups.17 We are not aware of any other comparable
data for adult players or of any study specifically investi-
gating the cervical isometric strength of the front-row
forwards. Using multivariate techniques, we previously
reported that player age, weight and grip strength (as an
objective measure of overall strength) was strongly pre-
dictive of isometric neck extension strength in the
general school-aged rugby playing population; explain-
ing around two-thirds of the variance in cervical
strength. Interestingly, in this analysis, the measure of
grip strength was not a strong predictor of cervical
strength in this specific group of front-row players,
where player weight and number of years of experience
of playing in the front row were the most important
factors. This finding may be a reflection of the general
lack of neck-specific training performed among rugby
players. Only 12 of the 52 players reported having per-
formed any neck-specific exercises. This may suggest
that the cervical strength of the players in this study was
developed from either generic strength training or from
specific scrum training. We propose that the elite
under-18 players had reached the same global strength
as their adult counterparts through peripheral strength
training; however, in the absence of specific structured
conditioning, they could not match the cervical strength
that the adults had gained as a result of years of com-
petitive scrummaging.

To the best of our knowledge, this is the first report of
a cervical musculature fatigue endurance assessment in
front-row rugby players of any age. In the absence of pre-
vious data, it was necessary to set a safe threshold at
which to perform the test; thus, the 50% submaximal
load held by the under-18 group (20 kg equivalent) was
significantly less than the adult 50% load (25 kg equiva-
 lent), as a result of their lower peak forces on the
maximal isometric testing. Now that these benchmark
data are available, we recommend that future fatigue
endurance assessment of under-18 players should be
performed using the mean adult 50% submaximal value
(25 kg equivalent), which would represent around 60%
of the average under-18 maximal isometric value found
in this study. It is most likely that greater differences
would be apparent between adults and under-18 groups
had we been able to employ this testing design and

†X² test.
further help discern those able to compete in the adult front row. Future work should also look at assessing ‘scrum-specific’ fatigue endurance, looking perhaps at repeated bouts of 80% submaximal testing over 10–15 s, which could be argued to better reflect the demands of this activity. We suggest this as an area for future research.

Preatoni et al assessed the forces generated in the scrum by 34 forward packs at six different playing grades (from senior school to international level) and found notable differences in the forces generated between schools and senior sides. Worryingly, these authors further reported that the combined compression and shear forces they recorded in the scrums were of a sufficient magnitude to induce chronic spine injury. Although further information is needed to understand the link between mechanical forces in the scrum and injury, the shear forces recorded are of particular concern as a risk factor for chronic degeneration of the spine through undesirable rotation and bending motions. The differences in strength characteristics between the adult and under-18 players we describe here suggest that appropriate and specific training interventions (perhaps through scrum training) are critical in developing the ability to modulate these forces at an individual level.

Perhaps of greater concern is the closed kinetic chain situation of the scrum, where the head is constrained from moving and loads are applied at both ends. This can lead to a buckling motion, a process particularly evident in front-row forwards when the scrum collapses and the head strikes the ground. If any single front-row player has comparatively weak cervical extensors, it is reasonable to suggest that this may enhance the risk of scrum collapse. We suggest that specific training may influence this; thus, younger players and perhaps also those returning from cervical injury are potentially at a competitive disadvantage.

For the safety of all six front-row players, it is important to recognise, understand and mitigate the biomechanical issues that occur in a closed kinetic chain situation where the forces cannot be vectored away from the spine.

A limitation of this study is the speculative link between cervical strength and scrum collapse and thus injury risk. Although the focus of our investigation was to consider cervical strength parameters, various other factors such as the speed and direction of force application and

Table 3  Multivariate predictive modelling of isometric neck extension ($R^2=0.31$)

| Predictor            | Coefficient | p Value |
|----------------------|-------------|---------|
| Front-row experience | 0.63        | 0.035   |
| Weight               | 0.22        | 0.003   |

Front-row experience is the primary predictor variable explaining 22% of the total variation; adding weight as a predictor determines the best-fit model (displayed above). Other variations offer less than 1% additional enhanced explanatory power with the limitation of comprising more predictor variables and were thus discounted.

orientation of the head/neck complex are also likely to have a bearing on the ability to modulate scrum forces. The neutral anatomic position was chosen for strength and fatigue testing from a safety point of view due to the lack of published data to determine alternative test design. The validity of this test position as the optimal assessment profile for rugby cervical testing is unknown. Future work should focus on the influence of the head position on strength and fatigue values in this context. It must also be recognised that recent changes to the laws of the game surrounding scrum engagement, depowering the contact strength and fatigue values in this context. It must also be fl

endurance parameters are now more critical than absolute production process for players wishing to play in the front row. vical strength pro

scrummaging. Objective measures of the individuals published in some countries as a means of ensuring that players their adult counterparts in terms of cervical strength. The cervical strength using alternative physical characteristics (and technical skill) to compete with adult players, our results suggest that policy should prevent players under the age of 18 playing in the front row of an adult match, unless specific criteria are met. In contrast to the general schoolboy population, predictive modelling of cervical strength using alternative physical characteristics was poor. As such, specific testing would need to be employed to identify those few individuals able to match their adult counterparts in terms of cervical strength. The concept of a passport to play in the front row is well established in some countries as a means of ensuring that players are appropriately equipped to cope with the rigours of scrumming. Objective measures of the individuals’ cervical strength profile should be an integral part of any selection process for players wishing to play in the front row.

Contributors All authors listed were involved in the study design and data acquisition. DFH performed the analysis and drafted the manuscript. All authors revised and approved the submission.

Funding This research received no specific grant from any funding agency in the public, commercial or not-for-profit sectors.

Competing interests DG has shares in Gatherer Systems who manufactured and supplied the testing equipment used in this study.

Ethics approval Regional ethics committee approval was received for the study through the Fife and Forth Valley REC.

Provenance and peer review Not commissioned; externally peer reviewed.

Data sharing statement No additional data are available.
