We observe a generic connection between LHC Higgs data and electroweak baryogenesis: the particle that contributes to the CP odd $hgg$ or $h\gamma\gamma$ vertex would provide the CP violating source during a first order phase transition. It is illustrated in the 2HDM that a common complex phase controls the lightest Higgs properties at the LHC, electric dipole moments and the CP violating source for electroweak baryogenesis. We perform a general parametrization of Higgs effective couplings and a global fit to the LHC Higgs data. We derive the modified EDM operators can be mediated by a weak-scale particle and the interplay between the Higgs properties and low energy EDMs and EDMs can be alleviated due to a cancellation with $\beta$ when the lightest Higgs boson, with a mass 125 GeV, is colored. The most familiar examples of $X$ include the top and gaugino-Higgsinos. It is definitely appealing if baryogenesis can be explained with the knowledge of electroweak scale physics. After the Higgs discovery, we enter a territory to measure or constrain the possible CPV sources responsible for $B$ in our universe.

In this letter, we perform a first study on the direct connection between the latest LHC results on Higgs properties and the baryon number generation from a common CPV phase. We work in a Two-Higgs-Doublet Model (2HDM) and the CP mediator $X$ is identified as the top quark. We study the electron and neutron EDMs and find the constraints on the same CP phase can be alleviated due to a cancellation with $\beta$ when the lightest Higgs boson, with a mass 125 GeV, is a mixture of CP even and odd states. We derive the modified Higgs coupling to other SM particles, and perform a global fit to the current data and extract the constraints on such a phase, which is still allowed to be nonzero, and even favored to be large with $\tan\beta \lesssim 1$. We study the electron and neutron EDMs and find the constraints on the same CP phase can be alleviated due to a cancellation with $\tan\beta \lesssim 1$. We show such a CP phase is capable of providing all the essential ingredients for EWBG. The future advances in precise measurements of Higgs properties, EDMs and refinements in EWBG calculations are anticipated to offer further interplays and pave the way for the genuine origin of CPV for baryon asymmetry.

2HDM and Sources of CP Violation. To be specific, we consider the type-II 2HDM, with the Higgs potential

$$V = \frac{\lambda_1}{2} (\phi_1^1 \phi_1^1)^2 + \frac{\lambda_2}{2} (\phi_2^1 \phi_2^1)^2 + \lambda_3 (\phi_1^1 \phi_1^1)(\phi_2^1 \phi_2^1) + \lambda_4 (\phi_1^1 \phi_2^1)(\phi_2^1 \phi_1^1) + \frac{1}{2} \left[ \lambda_5 (\phi_1^1 \phi_1^1)^2 + h.c. \right] \right)$$

where $F$ is the field strength of the gauge symmetry under which $X$ has a charge. In the early universe, during a strongly first order electroweak phase transition (SFO EWPT), $\xi$ can be space-time dependent through the bubble wall. For $SU(2)_L$, the first term in Eq. (1) creates a chemical potential and generates a net charge asymmetry $Q_X$: $\xi(x) F^F \sim \partial_t \xi(x) \cdot Q_X$, which is nothing but the CPV source for EWBG and $Q_X$ will be furthered reprocessed into baryon asymmetry ($B$) through weak sphaleron transitions. At zero temperature, the second term in Eq. (1) contributes to the CPV $h \rightarrow \gamma \gamma$ decay, or $gg \rightarrow h$ production if $X$ is colored. The most familiar examples of $X$ include the top and gaugino-Higgsinos. It is definitely appealing if baryogenesis can be explained with the knowledge of electroweak scale physics. After the Higgs discovery, we enter a territory to measure or constrain the possible CPV sources responsible for $B$ in our universe.

In this letter, we perform a first study on the direct connection between the latest LHC results on Higgs properties and the baryon number generation from a common CPV phase. We work in a Two-Higgs-Doublet Model (2HDM) and the CP mediator $X$ is identified as the top quark. We study the case when the lightest Higgs boson, with a mass 125 GeV, is a mixture of CP even and odd states. We derive the modified Higgs coupling to other SM particles, and perform a global fit to the current data and extract the constraints on such a phase, which is still allowed to be nonzero, and even favored to be large with $\tan\beta \lesssim 1$. We study the electron and neutron EDMs and find the constraints on the same CP phase can be alleviated due to a cancellation with $\tan\beta \lesssim 1$. We show such a CP phase is capable of providing all the essential ingredients for EWBG. The future advances in precise measurements of Higgs properties, EDMs and refinements in EWBG calculations are anticipated to offer further interplays and pave the way for the genuine origin of CPV for baryon asymmetry.
where $\phi_{1,2}$ are the two Higgs doublets. The tree-level flavor-changing neutral currents can be suppressed by imposing a $Z_2$ symmetry ($\phi_1 \rightarrow -\phi_1$ and $\phi_2 \rightarrow \phi_2$) which is softly broken by $m_{12}$. The only complex parameters are $\lambda_5$ and $m_{12}^2$ and we can set $\lambda_5$ real by proper rotation of $\phi_{1,2}$ phases. The corresponding Yukawa couplings respecting the $Z_2$ are

$$L_Y = \bar{Q}_L Y_D \phi_1 D_R + \bar{Q}_L Y_U (\tau_2) \phi_2^* U_R + \bar{L}_L Y_\phi \phi_1 E_R ,$$

(3)

where $D_R$ or $E_R$ ($U_R$) is defined to be odd (even) under the $Z_2$. The Higgs vacuum expectation values (VEV) are generally complex, with a relative phase $\xi$, $\langle \phi_1 \rangle = (0, v \cos \beta / \sqrt{2})^T$, $\langle \phi_2 \rangle = (0, v \sin \beta e^{i\xi} / \sqrt{2})^T$. The minimum condition of the potential solves $\xi$ from the phase of $m_{12}^2$ (recall $\lambda_5$ is real): $\text{Im}(m_{12}^2 e^{i\xi}) = (\lambda_5 \sin 2\xi)v^2 \sin \beta \cos \beta$ which means there exists one independent physical CP phase.

In this model, the source of CPV arises from the neutral Higgs sector (we define $\sqrt{2}\phi_0^0 = H_1^0 + iA_1^0$, $e^{-i\xi} \sqrt{2}\phi_0^0 = H_2^0 + iA_2^0$ with $H_1^0, A_1^0$ being real fields). Namely, the physical CP-odd state $A^0 = -\sin \beta A_1^0 + \cos \beta A_2^0$ will mix with the even states $H_1^0, H_2^0$. The mass square matrix $M$ in the basis of $(H_1^0, H_2^0, A^0)$ is diagonalized with a real orthogonal $R$, defined as $R M R^T = \text{diag}(M_{h_1}^2, M_{h_2}^2, M_{h_3}^2)$

$$R = \begin{pmatrix}
-s_\alpha c_{\alpha_b} & c_\alpha c_{\alpha_b} & s_{\alpha_b} \\
-s_\alpha s_{\alpha_b} - c_\alpha c_{\alpha_b} & -s_\alpha s_{\alpha_b} c_{\alpha_b} & s_{\alpha_b} \\
s_\alpha s_{\alpha_b} c_{\alpha_b} & c_\alpha s_{\alpha_b} c_{\alpha_b} & -c_{\alpha_b} 
\end{pmatrix}
$$

(4)

with $\alpha = \cos \alpha$, $s_\alpha = \sin \alpha$. In the CP conserving limit, $\alpha_{b,c} \rightarrow 0$. In the decoupling limit of second doublet, $\alpha \rightarrow \beta - \pi/2$ and $\alpha_{b,c} \rightarrow 0$. The lightest neutral scalar $h_1$, taken to be the SM-like Higgs, with mass $M_1 = 125$ GeV, is the following linear combination [12],

$$h_1 = -\sin \alpha \cos \alpha_0 H_1^0 + \cos \alpha \cos \alpha_0 H_2^0 + \sin \alpha_0 A^0.$$

Using the Yukawa coupling structure in Eq. (3), we obtained the couplings of $h_1$ to fermions

$$\mathcal{L}_{h_1, f f} = \frac{m_4}{v} h_1 \bar{c}_b (c_b + i\tilde{c}_b \gamma_5) b \bar{b} (c_b + i\tilde{c}_b \gamma_5) b,$$

(5)

where $c_\beta = \cos \alpha \cos \alpha_0 / \sin \beta$, $c_b = -\sin \alpha \cos \alpha_0 / \cos \beta$, $\tilde{c}_b = -\cot \beta \sin \alpha_0$, and $\tilde{c}_b = -\tan \beta \sin \alpha_0$. The interactions with gauge bosons $WW$ and $ZZ$ are

$$\mathcal{L}_{h_1, V V} = \cos \alpha_0 \sin(\beta - \alpha) \mathcal{L}_{h_1}^{SM} \mathcal{L}_{h_1}^{SM} V \equiv a \mathcal{L}_{h_1}^{MV}.$$

(6)

It is worth pointing out that the CPV coupling of $h_1$ only depends on $\alpha_b$, and is closely connected to the phase $\xi$. In order to make their relation more transparent, consider the case $m_{h_2} \approx m_{h_3} \gg m_{h_1}$, we find approximately $\tan \alpha_0 \approx -\lambda_5 \sin 2\xi v^2 / [m_{h_2}^2 + (\lambda_4 - \lambda_5 \cos 2\xi) v^2 / 2]$, where $h_2^+$ is the physical charged Higgs state. With the second doublet near the weak scale, we would expect $\alpha_0 \lesssim \xi$. This is the key relation that motivates our study below. The angle $\alpha_0$ are constrained by the Higgs property and the electric dipole moment experiments, while the phase $\xi$ is closely connected to the essential CPV source for EWBG.

FIG. 1: Global fits to the Higgs data for various values of $\tan \beta$. The global minima still prefers a non-vanishing $\alpha_b$ for $\tan \beta \lesssim 1$. The magenta region is excluded by electron EDM constraint before Nov. 2013. The latest ACME [13] exclusion ($d_e < 10.25 \times 10^{-29}$e cm at 95% CL) is given by the blue region which is a much stronger constraint.

**Higgs Properties as Indirect Probe.** From the derived interactions (5) and (6), we can obtain the modified Higgs production and decay rates at the LHC. The Higgs production via gluon fusion process could happen through both $h_1 GG$ and $h_1 GG$ operators in an incoherent way, after integrating out the CP conserving and violating $h_1 t \bar{t}, h_1 b \bar{b}$ interactions. The ratio of the two cross sections is $[13] [14]$

$$\frac{\sigma_{gg \rightarrow h_1}}{\sigma_{gg \rightarrow h_1}} = \frac{(1.03c_\xi - 0.06c_b)^2 + (1.57c_\xi - 0.06c_b)^2}{(1.03 - 0.06)^2},$$

(7)

for $m_{h_1} = 125$ GeV, and the production cross sections of $h_1$ via $W, Z$ boson fusion and in association with $W, Z$ are simply rescaled from the SM case by $\sigma_{VV \rightarrow h_1}^{SM} / \sigma_{VV \rightarrow h_1}^{SM}$. The heavy Higgs contributions are negligible.

The decay rates into gauge bosons are rescaled by $\Gamma_{h_1 \rightarrow WW} / \Gamma_{h_1 \rightarrow WW}^{SM} = \Gamma_{h_1 \rightarrow ZZ} / \Gamma_{h_1 \rightarrow ZZ}^{SM} = \alpha^2$. The decay rates into light fermions are approximately $\Gamma_{h_1 \rightarrow b \bar{b}} / \Gamma_{h_1 \rightarrow b \bar{b}}^{SM} = \Gamma_{h_1 \rightarrow t \bar{t}} / \Gamma_{h_1 \rightarrow t \bar{t}}^{SM} \approx c_\beta^2 + c_b^2$, by neglecting the final state masses. Similar to the gluon fusion case, the diphoton decay can be separated into CP conserving and violating parts

$$\frac{\Gamma_{h_1 \rightarrow \gamma \gamma}}{\Gamma_{h_1 \rightarrow \gamma \gamma}^{SM}} = \frac{(0.23c_\xi - 1.04c_b)^2 + (0.35c_\xi)^2}{(0.23 - 1.04)^2}.$$

(8)

Finally, for calculating the Higgs total decay width, the decay to gluons is $\Gamma_{h_1 \rightarrow gg} / \Gamma_{h_1 \rightarrow gg}^{SM} = \sigma_{gg \rightarrow h_1} / \sigma_{gg \rightarrow h_1}^{SM}$.

We make a global fit to the inclusive LHC Higgs data published in March 2013 [2] [4], taking into account the possibility of CPV in the Higgs sector. The most significant change in
the latest data is that CMS is no longer seeing an excess in the diphoton channel, while it still persists in the ATLAS result. Therefore, we decided to show both the separate and the combined fits to the ATLAS and CMS data. The best fit points in the effective coefficients \( a, c_t, \tilde{c}_t, \tilde{c}_t, \tilde{c}_b, \tilde{c}_b, \) and the 2HDM parameter \( \alpha, \alpha_b, \) for \( \tan \beta = 0.8 \) are presented in Table I. A more comprehensive analysis on the 2HDM parameter \( \alpha, \alpha_b \) and \( \tan \beta \) which includes the exclusion region from the EDM constraints (see below) is shown in Fig. 1. We find that SM always gives the best fit for \( \tan \beta > 1 \). For \( \tan \beta \lesssim 1 \), better fit points are found with a non-vanishing CP phase \( \alpha_b \).

In the presence of CPV Higgs couplings with the top quark \( \tilde{c}_t \), incoherent contributions in Eqs. (7) and (8) can modify both the production \( gg \rightarrow h_1 \) and the \( h_1 \rightarrow \gamma \gamma \) decay rate [16]. For smaller \( \tan \beta \lesssim 1 \) and \( \alpha \approx 0 \), larger \( \tilde{c}_t \) and smaller \( c_b, \tilde{c}_b \) can be achieved simultaneously, with an order one CP phase \( \alpha_b \). The resulting signal strengths are characterized by an enhanced diphoton rate, and a suppressed \( Vbb \) rate, both favored by ATLAS (see the first column of Fig. 1). The common features of such minima include: 1) enhanced effective \( hgg \) coupling, 2) suppressed \( \tilde{c}_t, \tilde{c}_b, \) \( \alpha \) couplings, and the effective \( h\gamma \gamma \) coupling, 3) reduced Higgs total width. These effects are optimized for \( \tan \beta \sim 1 \). On the other hand, the signals observed by CMS are SM-like. Therefore, the best fit point always lies close to SM. For \( \tan \beta < 1 \), a nonzero \( \alpha_b \) gives better fit, because it can accommodate the slight suppression in the \( WW \) and \( ZZ \) channel as observed by CMS.

**Electric Dipole Moments**

The mixing \( \alpha_b \) between the CP even and odd Higgs states leads to a series of low-energy CPV variables, among which we find the EDM of electron gives the leading constraints. The dominant contribution to electron EDM comes from the Barr-Zee type diagrams at two loop [12]. The lightest Higgs boson can mediate CPV from the top quark and \( W \) loops to the electron line [18,19].

\[
\left[ \frac{d_e}{e} \right]_i = \sqrt{2\alpha G_F m_e} F_1(z_i),
\]

(9)

where \( F_1(z_i) = (16/3) (f(z) \tan^2 \beta \text{Im} Z_2 - g(z) \cot^2 \beta \text{Im} Z_1) \) for top quark, \( (6f(z_w) + 10g(z_w))(\sin^2 \beta \tan^2 \beta \text{Im} Z_2 + \cos^2 \beta \text{Im} Z_1) \) for \( W \) boson, \( z_i = m_i^2/M_{h_i}^2 \) and the loop functions \( f(z) \) and \( g(z) \) can be found in [17]. The CPV variables \( F_1 Z_1, F_2 Z_2 [21] \) can be expressed in terms of \( c_e, \tilde{c}_e, c_t, \tilde{c}_t, a \) in Eqs. (5) and (6) for the Higgs global fits, \( \tan^2 \beta \text{Im} Z_2 = -\tilde{c}_b c_t, \cot^2 \beta \text{Im} Z_1 = \tilde{c}_t c_b \) and \( \left( \sin^2 \beta \tan^2 \beta \text{Im} Z_2 + \cos^2 \beta \text{Im} Z_1 \right) = \alpha_c. \) We neglect the contribution with a \( Z \)-boson connecting the electron line and top loop which is always less than 10% [20].

We find most of the time the top and \( W \)-loop contributions to electron EDM have opposite signs, and can be minimized simultaneously near \( \alpha \approx \beta \). The magnitude of the \( W \)-loop part is more sensitive to \( \tan \beta \), and the maximal cancellation happens near \( \tan \beta \sim 1 \). In these regimes, the electron EDM limit can be satisfied without suppressing the CPV phase \( \alpha_b \). These features are illustrated in Fig. 2. We use the 95% confidence level limit of the latest electron EDM measurement [22], \( d_e < 1.25 \times 10^{-27} \text{cm.} \) The exclusion in \( \alpha - \alpha_b \) plan is shown as the magenta region in Fig. 1. The neutron EDM constraint [23] from valence quark EDM, chromoelectric dipole moment and the Weinberg operators are also considered. We find that they do not impose any relevant constraint comparing to the electron EDM.

So far we have neglected the charged and other neutral Higgs states in both the Higgs fit and the EDM calculation. The charged Higgs mass is constrained by \( b \rightarrow s \gamma \) transition [24] and the measurement of the \( R_b \) at LEP [25,26] to be heavier than \( 300-400 \text{GeV} \). The bound can be significantly stronger if \( \tan \beta \) is far less than one [26,27].

**Electroweak Baryogenesis.** During a SFO EWPT, the top quark mass has a space-time dependent phase varying across the bubble wall. This results in a CPV source (for bottom quark case, see [56]) which can be estimated as [22,33]

\[
S(t) \approx \frac{3}{2\pi^2} \left( \frac{m_s}{v \sin \beta} \right)^2 v_T^2(t) \theta(t) v_w T,
\]

(10)

where we take \( L_w = 5/T, v_w = 0.02, \) and \( z < 0 \) (0) corresponds to unbroken (broken) side of the expanding bubble. We assume the following shapes of the bubble wall and the complex phase, \( v_T/T = \zeta T [1 + \tanh(z/L_w)]/2 \) and \( \theta(z) = \theta_{brk} - \Delta \theta [1 - \tanh(z/L_w)]/2 \) [54], where \( \Delta \theta \) is the change in the VEV’s phase across the wall. To get a SFO EWPT, \( \zeta \gtrsim O(1), \) the heavier neutral scalars are found to be heavier than \( 400 \text{GeV} [28,31], \) which is convenient to accommodate in the 2HDM with LHC data [31].

The imbalance between particle and antiparticle number densities caused by CPV prevails among the quarks and Higgs...
fields, through the top Yukawa interaction, mass term and strong sphaleron processes. This results in a net asymmetry in the left-handed fermion charge density \( n_L \) suppressed by \( \Gamma_{ss} \). Here we follow the semi-analytical calculation developed in \([32][33]\). The relevant thermal rates are \( \Gamma_{ss} = 16 \kappa^2 T^4 \) (with \( \kappa = 20 \) from \([35]\)), \( \Gamma_{ws} = 12 \kappa^2 T^4 \), \( \Gamma_n(z) \approx \Gamma_n(z) = (3/2 \pi^2) (m_t/v \sin \beta)^2 v_T^2(z)/T \). In the unbroken phase near the bubble, the weak sphaleron process converts \( n_L \) into baryon asymmetry, which is estimated as

\[
n_b = -\frac{3 \Gamma_{ws}}{2 v_w} \int_{-\infty}^{0} n_L(z) e^{15 \Gamma_{ws}/z} \frac{1}{(4 v_w) dz}.
\]

We find the observed baryon asymmetry to entropy density ratio \( \eta_b = n_b/s \approx (0.7 - 0.9) \times 10^{-10} \) \([37][38]\), can be obtained with \( \Delta \theta \approx 0.2 \) (\( \zeta_T \approx 1.5 \)). The value of \( \Delta \theta \) is solved numerically from the Higgs potential in Eq. \([2]\). It has been shown that \( \Delta \theta \) is of similar size to the zero temperature phase \( \xi \) for small \( m_{h_0} \) \([28][39]\), close to \( m_{h_0} = 125 \) GeV. Therefore it is convincing to assume \( \Delta \theta \approx \alpha_b \) and present the corresponding connection to EDM and Higgs global fits in Fig. \([3]\). We can see that successful EWBG sets a lower bound on the CPV phase. Such a phase will keep being probed directly or indirectly in the future LHC Higgs measurements and low energy experiments like EDM, and being used to test the viability of the EWBG scenario. We do notice though the final baryon number density is sensitive to the choices of \( v_w, \zeta_T \) and \( \Gamma_{ss} \), etc.. A more precise calculation of \( \eta_b \) would require improved determination of these quantities which involves higher-order and non-perturbative calculations.

**Direct Probe of CP Violation in Higgs sector.** Here we briefly discuss the prospects of measuring the CPV in the Higgs sector. The \( h \rightarrow ZZ \rightarrow 4 \ell \) process has been used to constrain the CP odd coupling to Z-boson \([40][42]\). Nevertheless, a relevant limit can not be obtained to any model since the observable is suppressed by the large tree level CP even coupling. The physical effects from CP odd and even operators in the 2\( \gamma \) or \( Z\gamma \) channel are comparable but such discriminations require better identification of photon polarization in the Bethe-Heitler process \([43]\). A more promising channel could be the gluon fusion production of \( h \) in together with two forward jets \([44]\) or the \( th \) production \([45]\). The virtual effect of a CPV Higgs coupling can also be probed in the top pair production with the leptonic decay channel \([46]\). We leave a systematic classification and quantitative study of these signatures employing the LHC data for a future work.

**Conclusion.** In summary, we elaborate the connection between the LHC data and EWBG in a 2HDM. We performed a global fit to the latest LHC Higgs data, and find a nonzero CP phase is favored for \( \tan \beta \lesssim 1 \). When combined with the electron and neutron EDM constraints, we find the phase is allowed to be as large as order one near \( \tan \beta \sim 1 \). We show that this phase can provide the CPV source for EWBG.

The future improvements in measuring the Higgs properties at LHC and the EDMs would enable us to probe the possible origin of CPV beyond the CKM matrix, that is connected to

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig3}
\caption{Values of \( \Delta \theta \) and \( \tan \beta \) consistent with the observed \( \eta_b \). We take the constraints from Fig. \([1]\) with \( \alpha = \beta - \pi/2 \), and \( \Delta \theta = \alpha_b \). The blue star point is the benchmark point from the numerical studies in \([28]\) \( \Delta \theta = \xi \approx 0.1 \) for \( m_{h_1} = 125 \) GeV and \( m_{h_2} = 400 \) GeV.}
\end{figure}

the baryon asymmetry of the universe.
