Filtration shrinkage, strict local martingales and the Föllmer measure

Martin Larsson
Swiss Finance Institute, EPFL

October 16, 2012

Abstract

When a strict local martingale is projected onto a subfiltration to which it is not adapted, the local martingale property may be lost, and the finite variation part of the projection may have singular paths. This phenomenon has consequences for arbitrage theory in mathematical finance. In this paper it is shown that the loss of the local martingale property is related to a measure extension problem for the associated Föllmer measure. When a solution exists, the finite variation part of the projection can be interpreted as the compensator, under the extended measure, of the explosion time of the original local martingale. In a topological setting, this leads to intuitive conditions under which its paths are singular. The measure extension problem is then solved in a Brownian framework, allowing an explicit treatment of several interesting examples.

1 Introduction

It is a simple fact that the optional projection of a martingale onto a subfiltration is again a martingale. However, for local martingales the situation is different, and this was the starting point for Föllmer and Protter in [9]. They consider, among other things, three-dimensional Brownian motion \( B = (B^1, B^2, B^3) \) starting from \((1, 0, 0)\), defined on a filtered probability space \((\Omega, \mathcal{G}, \mathbb{G}, P)\) where the filtration \(\mathbb{G}\) is generated by \(B\). In this setting they study optional projections of the process \( N = 1/\|B\| \) onto subfiltrations \(\mathbb{F}^1\) and \(\mathbb{F}^{1,2}\) generated by \(B^1\) and \((B^1, B^2)\), respectively. It is well-known that \(N\), the reciprocal of a BES(3) process, is a local martingale in \(\mathbb{G}\). The same turns out to be true for its optional projection onto \(\mathbb{F}^1\). However, the optional projection onto \(\mathbb{F}^1\) is not a local martingale. Indeed, it was shown in [9], Theorem 5.1, that the equality

\[
E^P [N_t \mid \mathcal{F}^1_t] = 1 + \int_0^t u_x(s, B^1_s) dB^1_s \left( \frac{1}{s} dt - \int_0^s \frac{1}{s} dL^0_s \right), \quad t \geq 0,
\]

holds \(P\)-a.s., where the function \(u\) is given by

\[
u(t, x) = \sqrt{\frac{2\pi}{t}} \exp \left( \frac{x^2}{2t} \right) \left( 1 - \Phi(\|x\|/\sqrt{t}) \right),
\]
and $L^0$ is the local time of $B^1$ at level zero. Here $\Phi(\cdot)$ is the standard Normal cumulative distribution function. A superficial reason for the appearance of the local time is the non-differentiability of $u$ at $x = 0$, but this is of course highly specific to this particular example. The main goal of the present paper is to shed further light on when the optional projection of a general positive local martingale $N$ fails to be a local martingale, and, when this is the case, what can be said about the behavior of its finite variation part. The basic structural result holds for arbitrary positive local martingales, subject only to a weak regularity condition on the filtration.

A crucial tool in the analysis is a variant of the Föllmer measure $Q_0$ associated with $N$, whose construction we briefly review in Section 2. A non-uniqueness property of (this variant of) the Föllmer measure leads us to formulate a measure extension problem (Problem 1): Find an extension $Q$ of $Q_0$ that is equivalent to $P$ on each $\sigma$-field of the subfiltration under consideration. When a solution exists, one can interpret the finite variation part of the projection of $N$ as the compensator of a certain stopping time (Theorem 1). This stopping time is the explosion time of $N$, which may be finite under the Föllmer measure.

These developments, valid in full generality, are carried out in Section 3. We then proceed in Section 4 to study filtrations generated by the image under some continuous map of the coordinate process $Y$ (we now restrict ourselves to path space), and take $N$ to be a deterministic function of $Y$. This additional structure makes it possible to obtain more detailed results about the points of increase of the finite variation part of the projection of $N$ (Theorem 2). As a consequence (Corollary 2) we obtain a simple sufficient condition for its paths to be singular. Next, in Section 5 we address the problem of actually finding a solution to the measure extension problem. The setting is now restricted further: the coordinate process is assumed to be (multidimensional) Brownian motion under $P$. In this framework we derive explicit conditions under which the measure extension problem can be solved (Theorem 3). Several illustrating examples are given in Section 6 including the aforementioned example of Föllmer and Protter.

Strict local martingales are fundamental in financial models for asset pricing bubbles and so-called relative arbitrage, see for instance [11, 13, 7, 12, 17]. The role of filtration shrinkage in this context, in particular the loss of the local martingale property, is discussed in [9]. The authors explain how less informed investors may perceive arbitrage opportunities where there are none. Applications in credit risk include [2] and [14] (the latter relying on the very nice theory article [24]). More generally, filtration shrinkage appears naturally in models with restricted information, and results such as those obtained in the present paper will be instrumental for developing models of this type.

1.1 Notation

Let us now fix some notation that will be in force throughout the paper. $(\Omega, \mathcal{G}, \mathcal{G}, P)$ is a filtered probability space, where the filtration $\mathcal{G} = (\mathcal{G}_t)_{t \geq 0}$ is the right-continuous modification of a standard system. That is, $\mathcal{G}_t = \cap_{u > t} \mathcal{G}_u^0$, where each $\mathcal{G}_t^0$ is Standard Borel (see Parthasarathy [22], Definition V.2.2) and any decreasing sequence of atoms has
a non-empty intersection\(^1\). We always assume that \( \mathcal{G} = \mathcal{G}_\infty = \bigvee_{t \geq 0} \mathcal{G}_t \). A key example of a standard system is the filtration generated by all right-continuous paths, allowed to explode to an absorbing cemetery state in finite time, and with left limits prior to the explosion time. This example is considered in detail in [20], and will re-appear in Section 4 of the present paper. Note that we do not augment \( \mathcal{G} \) with the \( \mathcal{P} \)-nullsets—but this does not cause any serious complications, due to the following result.

**Lemma 1** Let \( R \) be a probability measure on \( \mathcal{G} \), and denote by \((\overline{\mathcal{G}}, \mathcal{G})\) the augmentation of \((\mathcal{G}, \mathcal{G})\) with respect to \( R \). Then

(i) Every \( \overline{\mathcal{G}} \) optional (predictable) process is \( R \)-indistinguishable from a \( \mathcal{G} \) optional (predictable) process.

(ii) Every right-continuous \((\mathcal{G}, R)\) martingale is a \((\overline{\mathcal{G}}, R)\) martingale.

**Proof.** Part (i) is Lemma 7 in Appendix 1 of [6]. Part (ii) follows from Theorem IV.3 in the same reference. ■

Next, let \( N \) be a local martingale on \((\Omega, \mathcal{G}, \mathcal{G}, \mathcal{P})\) with \( N_0 = 1 \) and càdlàg paths that are strictly positive \( \mathcal{P} \)-a.s. Define stopping times

\[
\tau_n = n \land \inf \{ t \geq 0 : N_t \geq n \}, \quad \tau_0 = \lim_{n \to \infty} \tau_n.
\]

Since \( N \) is a local martingale under \( \mathcal{P} \), and hence does not explode in finite time, we have \( \mathcal{P}(\tau_0 < \infty) = 0 \). However, there may be \( \mathcal{P} \)-nullsets on which \( \tau_0 \) in finite—in particular this is the case when \( N \) is a strict local martingale, as will become clear when we discuss the Föllmer measure.

The reciprocal of \( N \) will play a sufficiently important role that it merits its own notation. We thus define a process \( M \) by

\[
M_t = \frac{1}{N_t} 1_{\{\tau_0 > t\}}. \tag{2}
\]

Finally, note that \( \mathcal{G}_{\tau_0} = \bigvee_{n \geq 1} \mathcal{G}_{\tau_n} \), see for instance [5], Theorem IV.56(d).

---

2 The Föllmer measure

Following similar ideas as in Delbaen and Schachermayer [4] and Pal and Protter [21], which originated with the paper by Föllmer [8], we can construct a new probability \( Q_0 \) on \( \mathcal{G}_{\tau_0} \) as follows. For each \( n \geq 1 \), the stopped process \( N_{\tau_n} = (N_{t \wedge \tau_n})_{t \geq 0} \) is a strictly positive uniformly integrable martingale, so we may define a probability \( Q_n \sim \mathcal{P} \) on \( \mathcal{G}_{\tau_n} \) by \( dQ_n = N_{\tau_n} dP \). The optional stopping theorem and uniform integrability yield

\[
N_{\tau_n} = N_{\tau_n + 1} = E^P [N_{\tau_n + 1} | \mathcal{G}_{\tau_n}] = E^P \left[ N_{\tau_n + 1} | \mathcal{G}_{\tau_n} \right].
\]

\(^1\)This means that if \((t_n)_{n \geq 0}\) is a nonnegative increasing sequence, \( A_n \in \mathcal{G}_{t_n} \) is an atom for each \( n \geq 1 \), and \( A_n \supset A_{n+1} \), then \( \cap_n A_n \neq \emptyset \).
The measures \((Q_n)_{n \geq 1}\) thus form a consistent family. Next, by Remark 6.1 in the Appendix of [8], \((G_{\tau_n})_{n \geq 1}\) is a standard system, so Parthasarathy’s extension theorem (Theorem V.4.2 in [22]) applies: there exists a probability measure \(Q_0\) on \(G_{\tau_0}\) that coincides with \(Q_n\) on \(G_{\tau_n}\), for each \(n\).

From now on, \(Q_0\) will denote the measure on \(G_{\tau_0}\) obtained from \(P\) in this way.

Here is the key point: \(Q_0\) is only defined on \(G_{\tau_0}\), not on all of \(G\). There are typically many ways in which \(Q_0\) can be extended to a measure \(Q\) on \(G\), and we will see that the choice of extension is crucial in the context of filtration shrinkage. In particular, the existence of an extension with certain properties is intimately connected with the behavior of the optional projection of \(N\) (under \(P\)) onto smaller filtrations \(F \subset G\).

The following lemma shows that no matter which extension \(Q\) one chooses, \(M\) defined in (2) is always the density process relative to \(P\). In particular it is a (true) \(P\) martingale.

**Lemma 2** Suppose \(Q\) is an extension of \(Q_0\) to all of \(G\). Then, for each \(t \geq 0\),

\[ M_t = \frac{dP}{dQ} \bigg|_{G_t} \quad Q\text{-a.s.} \]

**Proof.** The argument is well-known. Fix \(t \geq 0\) and pick \(A \in G_t\). Using that \(M_t = 0\) for \(t \geq \tau_0\), monotone convergence, and the fact that \(M_t \wedge \tau_n = \frac{dP}{dQ} \bigg|_{G_t \wedge \tau_n}\) (which relies on the strict positivity of \(N\)), we obtain

\[
E^Q [M_t 1_A] = E^Q [M_t 1_{A \cap \{\tau_0 > t\}}] = \lim_{n \to \infty} E^Q [M_t 1_{A \cap \{\tau_n > t\}}] = \lim_{n \to \infty} P(A \cap \{\tau_n > t\}) = P(A \cap \{\tau_0 > t\}).
\]

Since \(P(\tau_0 > t) = 1\), the right side equals \(P(A)\), as claimed.

If \(N\) is a strict local martingale under \(P\), then \(Q(\tau_0 < \infty) > 0\), and vice versa. To see this, simply write

\[ Q(\tau_0 > t) = E^Q[M_t N_t] = E^P[N_t], \]

which is strictly less than one for some \(t > 0\) if and only if \(N\) is a strict local martingale. Our focus will be on this case, and in particular this means that \(P\) and \(Q\) cannot be equivalent. In fact, they may even be singular, which is the case if \(Q(\tau_0 < \infty) = 1\). On the other hand, Lemma 2 guarantees that we always have local absolute continuity: for each \(t\), \(Q|_{G_t} \ll P|_{G_t}\). “Global” absolute continuity, \(Q \ll P\), holds when \((M_t)_{t \geq 0}\) is uniformly integrable under \(P\).

The following simple but useful result shows that although \(N\) may explode under \(Q\), it does so continuously—it does not jump to infinity.

**Lemma 3** On \(\{\tau_0 < \infty\}\), the equality \(M_{\tau_0} = 0\) holds \(Q_0\)-a.s.
**Proof.** First, note that $\tau_n < \tau_0$ $Q_0$-a.s. Indeed, since $N^{\tau_n}$ is a martingale under $P$ and $\tau_n$ is bounded by construction,

$$Q_0(\tau_n < \tau_0) = E^{Q_0}[M_{\tau_n} N_{\tau_n}] = E^P[N_{\tau_n}] = 1.$$  

Now, on $\{N_{\tau_0} - < \infty$ and $\tau_0 < \infty\}$ there exists a (large) $n$ such that $\tau_n = \tau_0$. Hence

$$Q_0(\tau_0 < \infty) = E^{Q_0}[N_{\tau_0} - < \infty] = \sum_{n \geq 1} Q_0(\tau_n = \tau_0) = 0.$$  

Therefore $Q_0(M_{\tau_0} - > 0$ and $\tau_0 < \infty) = 0$, as claimed. 

Let us mention that the construction of $P$ from $Q$ is straightforward: assuming that $M$ is a $Q$ martingale, the measures $P_n$ on $\mathcal{G}_n$ given by $dP_n = M_n dQ$ form a consistent family, extendable to a measure $P$ on $\mathcal{G}$ using Parthasarathy’s theorem. Local absolute continuity is immediate, and “global” absolute continuity holds when $M$ is uniformly integrable. Note that $P$ only depends on the behavior of $Q$ on $G_{\tau_0}$, since $P(\tau_0 = \infty) = 1$.

We finally comment on how the question of uniqueness has been treated previously in the literature. In Föllmer’s original paper [8], a measure is constructed on the product space $(0, \infty) \times \Omega$, specifically on the predictable $\sigma$-field. This measure assigns zero mass to the stochastic interval $(\tau_0, \infty]$, which is key to obtaining uniqueness. On the other hand, neither [4] nor [21] consider the product space, but work directly on $\Omega$. However, $N$ is now taken to be the coordinate process, with $+\infty$ as an absorbing state. Hence there is “no more randomness” contained in the probability space after $\tau_0$, which gives uniqueness of $Q$. In the recent paper [16], Kardaras et al. consider more general probability spaces, and in particular discuss the question of non-uniqueness. A construction of the Föllmer measure when the local martingale $N$ may reach zero is discussed in [1].

### 3 Filtration shrinkage and a measure extension problem

Consider now a filtration $F = (\mathcal{F}_t)_{t \geq 0}$ with $\mathcal{F}_t \subset \mathcal{G}_t$, $t \geq 0$, assumed to be the right-continuous modification of a standard system. Again, completeness is not assumed. The focus of this paper is on the object

$$E^Q[N_t | \mathcal{F}_t], \quad t \geq 0,$$

interpreted as the optional projection of $N$ onto $F$ (see below).

We suppose that $Q$ is an extension of $Q_0$ as discussed in Section 2. By Theorem 6 in Appendix 1 of [6], optional projections of $N$ and $M$ exist under $P$ and $Q$, respectively. When we write $E^P[N_t | \mathcal{F}_t]$ and $E^Q[M_t | \mathcal{F}_t]$ we always refer to these optional projections. Moreover, the projections have càdlàg paths. This follows from the càdlàg property of the optional projections onto the augmentation of $F$ (under $P$ respectively $Q$), together with Lemma 1 and the uniqueness of the projection. A subtlety arises here: the optional projection of $N$ under $P$ is unique up to a $P$-evanescent set. However, this set need not be $Q$-evanescent. We will return to this issue momentarily, see Remark 1 below.
however, we introduce the following measure extension problem, which turns out to be intimately related to properties of the optional projections.

**Problem 1 (Measure extension problem)** Given the probability $Q_0$ constructed in Section 2 and the subfiltration $\mathbb{F} \subset \mathbb{G}$, find a probability $Q$ on $(\Omega, \mathcal{G})$ such that

(i) $Q = Q_0$ on $\mathcal{G}_{\tau_0}$

(ii) The restrictions of $P$ and $Q$ to $\mathcal{F}_t$ are equivalent for each $t \geq 0$.

**Remark 1** The issue of $Q$-non-uniqueness of the optional projection of $N$ under $P$ is resolved if $Q$ solves the measure extension problem. Because, if $N'$ and $N''$ are two versions of $E_P[N_t | \mathcal{F}_t]$, then for every $T \geq 0$, $(N'_t)_{t \leq T}$ and $(N''_t)_{t \leq T}$ coincide on a set $A_T$ with $P(A_T) = 1$. But $A_T \in \mathcal{F}_T$, so $Q(A_T) = 1$ as well. It follows that $N' = N''$ $Q$-a.s.

**Remark 2** If $N$ is a true martingale, then $Q_0(\tau_0 = \infty) = 1$, and the measure extension problem has a trivial solution: take $Q = Q_0$. Of course, for us the interesting case is when $N$ is a strict local martingale.

The following result clarifies the link between the measure extension problem and filtration shrinkage.

**Lemma 4** Fix $t \geq 0$, and let $Q$ be any extension to $\mathcal{G}$ of $Q_0$. Then the following are equivalent.

(i) The restrictions of $P$ and $Q$ to $\mathcal{F}_t$ are equivalent.

(ii) $E^Q[M_t | \mathcal{F}_t] > 0$, $Q$-a.s.

(iii) $Q(\tau_0 | \mathcal{F}_t) > 0$, $Q$-a.s.

If either of the above conditions holds, then

$$Q(\tau_0 > t | \mathcal{F}_t) = E^Q[M_t | \mathcal{F}_t] E^P[N_t | \mathcal{F}_t], \quad P \text{- and } Q \text{-a.s.} \quad (3)$$

**Proof.** The equivalence of (i) and (ii) is immediate, since $E^Q[M_t | \mathcal{F}_t]$ is the Radon-Nikodym density of $P|_{\mathcal{F}_t}$ with respect to $Q|_{\mathcal{F}_t}$. We now prove that (ii) and (iii) are equivalent. To this end, let $A = \{E^Q[M_t | \mathcal{F}_t] = 0\} \in \mathcal{F}_t$. In the following, inclusions and equalities are understood up to $Q$-nullsets. We have

$$E^Q[1_A M_t] = E^Q[1_A E^Q[M_t | \mathcal{F}_t]] = 0,$$

so $M_t = 0$ on $A$. Hence $\tau_0 \leq t$ on $A$, so

$$E^Q[1_A Q(\tau_0 > t | \mathcal{F}_t)] = Q(A \cap \{\tau_0 > t\}) = 0,$$

and we deduce that $Q(\tau_0 > t | \mathcal{F}_t) = 0$ on $A$. The reverse inclusion, $\{Q(\tau_0 > t | \mathcal{F}_t) = 0\} \subset A$, is proved similarly, and this gives (ii) $\iff$ (iii). To prove formula (3), we use
that $P(\tau_0 > t) = 1$, Bayes’ rule, and the fact that $\frac{dP}{dQ}\big|_{\mathcal{F}_t} = M_t$ (Lemma 2) to get

$$E^P[N_t \mid \mathcal{F}_t] = E^P\left[\frac{1}{M_t}1_{\{\tau_0 > t\}} \mid \mathcal{F}_t\right] = \frac{E^Q\left[M_t1_{\{\tau_0 > t\}} \mid \mathcal{F}_t\right]}{E^Q[M_t \mid \mathcal{F}_t]} = \frac{Q(\tau_0 > t \mid \mathcal{F}_t)}{E^Q[M_t \mid \mathcal{F}_t]}.$$ 

This gives the desired conclusion. ■

A solution $Q$ to the measure extension problem, when it exists, leads to an interpretation of the finite variation part of the $P$ optional projection onto $\mathcal{F}$ of the local martingale $N$. To see how, let us define

$$Z_t = Q(\tau_0 > t \mid \mathcal{F}_t).$$

This is an $(\mathcal{F},Q)$ supermartingale, therefore it has a càdlàg modification since $\mathcal{F}$ is right-continuous. We choose this modification when defining $Z$. If in addition it is strictly positive, it has a multiplicative Doob-Meyer decomposition

$$Z_t = e^{-\Lambda_t}K_t,$$

where $\Lambda$ is nondecreasing, predictable, of finite variation with $\Lambda_0 = 0$, and $K$ is an $(\mathcal{F}, Q)$ local martingale with $K_0 = 1$.

**Proposition 1** Suppose $Q$ is a solution to the measure extension problem (Problem 7). Then $E^P[N_t \mid \mathcal{F}_t]$ is an $(\mathcal{F}, P)$ supermartingale, with multiplicative decomposition

$$E^P[N_t \mid \mathcal{F}_t] = e^{-\Lambda_t}U_t,$$

where $\Lambda$ is as in (4) and $U$ is an $(\mathcal{F}, P)$ local martingale. It is a true martingale provided $K$ in (4) is a true $(\mathcal{F}, Q)$ martingale.

**Proof.** If $Q$ solves the measure extension problem, Lemma 4 implies that $Z$ is strictly positive, so that the decomposition (4) exists. It also implies that

$$E^Q[M_t \mid \mathcal{F}_t]e^{\Lambda_t}E^P[N_t \mid \mathcal{F}_t] = K_t,$$

an $(\mathcal{F}, Q)$ local martingale. Since $E^Q[M_t \mid \mathcal{F}_t] = \frac{dP}{dQ}\big|_{\mathcal{F}_t}$ it follows that $e^{\Lambda_t}E^P[N_t \mid \mathcal{F}_t]$ is an $(\mathcal{F}, P)$ local martingale, and a true martingale if $K$ is. Denoting this process by $U$ yields the claimed decomposition. ■

**Remark 3** The fact that $E^P[N_t \mid \mathcal{F}_t]$ is an $(\mathcal{F}, P)$ supermartingale also follows from Theorem 2.3 in [9]. Moreover, it is of Class (DL) whenever $U$ is a martingale; and by Proposition 1 this holds if $K$ is a martingale. A simple sufficient condition for this is that $\Lambda$ does not increase too rapidly, in the sense that $E^Q[e^{\Lambda_t}] < \infty$ for each $t \geq 0$. Indeed, in this case $E^Q[\sup_{s \leq t} K_s] < \infty$ since $Z \leq 1$, implying the martingale property.

The following corollary is simple but nonetheless informative, since it shows that the measure extension problem certainly does not always have a solution.
Corollary 1 Suppose $N$ is a strict $(\mathbb{G}, P)$ local martingale. If $E^P[N_t | \mathcal{F}_t]$ is again an $(\mathbb{F}, P)$ local martingale, then the measure extension problem has no solution.

Proof. Suppose a solution exists. Then, since $E^P[N_t | \mathcal{F}_t]$ is a local martingale, the process $\Lambda$ in Proposition 1 is identically zero, so that $K$ is bounded and hence a true martingale. Therefore $E^P[N_t | \mathcal{F}_t] = U_t$ is a true martingale by Proposition 1. It follows that $E^P[N_t] = E^P[E^P[N_t | \mathcal{F}_t]] = 1$ for all $t \geq 0$, contradicting that $N$ is a strict local martingale.

We can now establish our first main result. It shows that the finite variation part $\Lambda$ appearing when $N$ is projected onto the smaller filtration can be interpreted as the predictable compensator of $\tau_0$, viewed in the appropriate filtration. The key step is an application of the Jeulin-Yor theorem from the theory of filtration expansions.

Theorem 1 Let $\mathbb{F}^{\tau_0}$ be the progressive expansion of $\mathbb{F}$ with $\tau_0$, that is, the smallest filtration that contains $\mathbb{F}$, satisfies the usual hypotheses (with respect to $Q$), and makes $\tau_0$ a stopping time. If $Q$ solves the measure extension problem, then

(i) the process

$$1_{\{\tau_0 \leq t\}} - \int_0^{t \wedge \tau_0} d\Lambda_s$$

is an $(\mathbb{F}^{\tau_0}, Q)$ uniformly integrable martingale, where $\Lambda$ is as in (1).

(ii) $\tau_0$ is not $\mathbb{F}^{\tau_0}$-predictable, provided $Q(\tau_0 < \infty) > 0$.

Proof. The proof uses stochastic integration, which assumes the usual hypotheses. This causes no complications: by Lemma 1, we may first pass to the $Q$-completion $\overline{\mathbb{F}}$ of $\mathbb{F}$ without losing the semimartingale property of any of the processes involved, carry out the computations there, and then go back to $\mathbb{F}$ at the cost of changing things on a $Q$-nullset.

The integration by parts formula yields

$$Z_t = 1 + \int_0^t e^{-\Lambda_s - dK_s} + [e^{-\Lambda_s}, K]_t - \int_0^t e^{-\Lambda_s - K_s - d\Lambda_s}.$$

By Yoeurp’s lemma ([6], Theorem VII.36), $[e^{-\Lambda_s}, K]$ is a local martingale, so we have the additive Doob-Meyer decomposition $Z_t = \mu_t - a_t$, where

$$\mu_t = 1 + \int_0^t e^{-\Lambda_s - dK_s} + [e^{-\Lambda_s}, K]_t \quad \text{and} \quad a_t = \int_0^t Z_s - d\Lambda_s.$$

By the Jeulin-Yor Theorem (see Theorem 1.1 in [10], or the original paper [15]), the process

$$1_{\{\tau_0 \leq t\}} - \int_0^{t \wedge \tau_0} \frac{1}{Z_s - da_s}$$

is an $(\mathbb{F}^{\tau_0}, Q)$ martingale, and indeed uniformly integrable since it is the martingale part of the Doob-Meyer decomposition of the Class (D) submartingale $1_{\{\tau_0 \leq \cdot\}}$. Substituting for $da_s$ yields (i).
To prove \((ii)\), assume for contradiction that there is a strictly increasing sequence of \(\mathbb{F}^{\tau_0}\) stopping times \(\rho_n\) such that \(\lim_n \rho_n = \tau_0\). By the Lemma on page 370 in \([23]\), there are \(\mathbb{F}\) stopping times \(\sigma_n\) such that \(\sigma_n \land \tau_0 = \rho_n \land \tau_0\). But since \(\rho_n < \tau_0\), this yields \(\sigma_n = \rho_n\). It follows that \(\tau_0\) is \(\mathbb{Q}\)-a.s. equal to an \(\mathbb{F}\) stopping time, implying that \(\mathbb{Q}(\tau_0 > t \mid \mathcal{F}_t) = 1_{\{\tau_0 > t\}}\) \(\mathbb{Q}\)-a.s.

This contradicts the assumption that \(\mathbb{Q}\) solves the measure extension problem, since by hypothesis \(\mathbb{Q}(\tau_0 < \infty) > 0\).

The significance of Theorem 1 is that it shows when the \((\mathbb{F}, \mathbb{P})\) supermartingale \(\mathbb{E} = \mathbb{P}[N_t \mid \mathcal{F}_t]\) loses mass: it happens exactly when the compensator of \(\tau_0\) increases, i.e., when there is an increased probability, conditionally on \(\mathbb{F}\), that \(\tau_0\) has already happened. This corresponds to a kind of smoothing over time of the sets \(\{\tau_0 \leq t\}\) when we pass to the smaller filtration \(\mathbb{F}\). This smoothing is necessary to make the restrictions of \(\mathbb{P}\) and \(\mathbb{Q}\) equivalent, since \(\{\tau_0 \leq t\}\) is \(\mathbb{P}\)-null but not necessarily \(\mathbb{Q}\)-null.

### 4 The finite variation term in a topological setting

In this section we specialize the previous setup as follows. Let \(E\) be a locally compact topological space with a countable base, and define \(E_\Delta = E \cup \{\Delta\}\), where \(\Delta \not\in E\) is an isolated point. We take \(\Omega\) to be all right-continuous paths \(\omega: \mathbb{R}_+ \to E_\Delta\) that are absorbed at \(\Delta\) (i.e., if \(\omega(s) = \Delta\) then \(\omega(t) = \Delta\) for all \(t \geq s\)) and have left limits on \((0, \zeta(\omega))\), where the absorption time \(\zeta\) is defined by

\[
\zeta(\omega) := \inf\{t \geq 0 : \omega(t) = \Delta\}.
\]

Let \(Y_t(\omega) = \omega(t)\) be the coordinate process, and define \(G_\omega = \sigma(Y_s : s \leq t)\). Then \(G_\omega = (G_\omega^t)_{t \geq 0}\) is a standard system, see the Appendix in \([8]\). We let \(G\) be the right-continuous modification of \(G_\omega\), and \(G = \bigvee_{t \geq 0} G_t\).

The \(\mathbb{P}\) local martingale \(N\) is assumed to be of the form

\[
N_t = \frac{1}{h(Y_t)} 1_{\{\tau_0 > t\}}
\]

for some function \(h: E_\Delta \to [0, \infty)\) that is continuous on \(E\) and satisfies \(h(Y_0) = 1\). The objects \(\tau_n\) \((n \geq 0)\), \(M\), and \(Q_0\) are defined as in Sections 1 and 2.

To describe the smaller filtration \(\mathbb{F}\), let \(D\) be a metrizable topological space, and let \(\pi: E \to D\) be a continuous map. We define \(D_\Delta = D \cup \{\Delta\}\) (assuming without loss of generality that \(\Delta \not\in D\)), and set \(\pi(\Delta) = \Delta\). If \(d(\cdot, \cdot)\) is a metric on \(D\), we extend it \(D_\Delta\) by setting \(d(x, \Delta) = d(\Delta, x) = \infty\) for \(x \in D\), and \(d(\Delta, \Delta) = 0\). Next, define a \(D_\Delta\)-valued process \(X\) by

\[
X_t = \pi(Y_t), \quad t \geq 0.
\]
It is clear that $X$ is $\mathcal{G}$-adapted. The filtration $\mathbb{F} = (\mathcal{F}_t)_{t \geq 0}$, given by

$$\mathcal{F}_t = \bigcap_{u > t} \sigma(X_s : s \leq u),$$

is therefore a subfiltration of $\mathcal{G}$, right-continuous, but not augmented. The structure imposed by the above conditions (and the flavor of the main theorem below) is primarily of a topological nature, which motivates the title of this section.

Recall the multiplicative decomposition $E^P[N_t \mid \mathcal{F}_t] = e^{-\Lambda_t} U_t$ of the positive $(\mathbb{F}, P)$ supermartingale $E^P[N_t \mid \mathcal{F}_t]$. The finite variation part $\Lambda$ is related to $\tau_0$ by Proposition 1, provided the measure extension problem has a solution. In the particular setting of the present section, we can say the following about the points of increase of $\Lambda$:

**Theorem 2** Assume that $Q$ is a solution to the measure extension problem, and let $\Lambda$ be as in (4). Then the random measure $d\Lambda_t$ is supported on the set $\{t : X_t \in \overline{D_0}\}$, where $D_0$ is the closure in $D$ of $D_0 = \pi \circ h^{-1}(\{0\}) = \{x \in D : x = \pi(y) \text{ for some } y \in E \text{ with } h(y) = 0\}$.

The proof requires two lemmas.

**Lemma 5** We have $\pi(Y_{\tau_0-}) \in D_0$ on $\{\tau_0 < \infty\}$, $Q_0$-a.s.

**Proof.** To show that $\pi(Y_{\tau_0-}) \in D_0$, one must find $y \in E$ with $h(y) = 0$ such that $\pi(y) = \pi(Y_{\tau_0-})$. But $h(Y_{\tau_0-}) = M_{\tau_0-} = 0$ on $\{\tau_0 < \infty\}$ by Lemma 3, so we may take $y = Y_{\tau_0-}$. ■

**Lemma 6** For any $\mathbb{F}$ stopping time $\rho$, the equality $Z_{\rho} = Q(\tau_0 > \rho \mid \mathcal{F}_{\rho})$ holds on $\{\rho < \infty\}$, $Q$-a.s.

**Proof.** We need to show that $E^Q[Z_{\rho}1_A \mid \{\rho < \infty\}] = Q(A \cap \{\tau_0 > \rho \text{ and } \rho < \infty\})$ for every $\mathbb{F}$-stopping time $\rho$ and every $A \in \mathcal{F}_{\rho}$. This clearly holds when $\rho$ is constant. Suppose now that $\rho$ is of the form

$$\rho = \sum_{i=1}^n t_i 1_{A_i},$$

where $t_i \in [0, \infty]$, $A_i \in \mathcal{F}_{t_i}$, and the $A_i$ constitute a partition of $\Omega$. Then

$$E^Q[Z_{\rho}1_A] = \sum_{i=1}^n E^Q[Z_{t_i}1_{A_i \cap A}]$$

$$= \sum_{i=1}^n Q(A \cap A_i \cap \{\tau_0 > t_i \text{ and } t_i < \infty\})$$

$$= Q(A \cap \{\tau_0 > \rho \text{ and } \rho < \infty\}),$$

where the second equality used that $A_i \cap A \in \mathcal{F}_{t_i}$ and that the result holds for constant times. Finally, let $\rho_n$ be a decreasing sequence of stopping times of the form (5) with
\[ \lim_{n} \rho_n = \rho. \] Right-continuity together with bounded convergence and the result applied to \( \rho_n \) now yields the statement of the lemma.

**Proof of Theorem 2.** Let \( 0 < \rho \leq \sigma \) be bounded \( \mathbb{F} \) stopping times such that \( X_\rho \not\in D_0 \) on \( [\rho, \sigma) \). We claim that \( \Lambda_\sigma - \Lambda_\rho = 0 \), \( Q \)-a.s. To prove this, first write

\[ \Lambda_\sigma - \Lambda_\rho = (\Lambda_\sigma - \Lambda_\rho)1_{\{\tau_0 \leq \rho\}} + (\Lambda_\sigma \wedge \tau_0 - \Lambda_\rho \wedge \tau_0)1_{\{\sigma < \tau_0\}}. \]  

(6)

By continuity of \( \pi \) and the choice of \( \rho \) and \( \sigma \), we have

\[ \pi(Y_{\tau_0}) = X_{\tau_0} \not\in D_0 \] on \( \{\rho < \tau_0 \leq \sigma\} \).

But according to Lemma 5, \( \pi(Y_{\tau_0}) \in D_0 \) on \( \{\tau_0 < \infty\} \), \( Q \)-a.s., so we get

\[ Q\left(\rho < \tau_0 \leq \sigma\right) \leq Q\left(\pi(Y_{\tau_0}) \not\in D_0, \tau_0 < \infty\right) = 0. \]  

(7)

Next, consider the filtration \( \mathbb{F}^{\tau_0} \) described in Theorem 1. By that theorem,

\[ 1_{\{\tau_0 \leq t\}} - \int_{0}^{t \wedge \tau_0} d\Lambda_s \] is an \((\mathbb{F}^{\tau_0}, Q)\) martingale. Since \( \rho \) and \( \sigma \) are also \( \mathbb{F}^{\tau_0} \) stopping times, the martingale property and the optional sampling theorem, together with (7), yield

\[ E^Q[\Lambda_{\sigma \wedge \tau_0} - \Lambda_{\rho \wedge \tau_0}] = E^Q[1_{\{\rho < \tau_0 \leq \sigma\}}] = 0. \]

Since \( \Lambda \) is nondecreasing, we deduce that \( \Lambda_{\sigma \wedge \tau_0} - \Lambda_{\rho \wedge \tau_0} = 0 \), \( Q \)-a.s. Using this in the decomposition (6), we obtain

\[ \Lambda_\sigma - \Lambda_\rho = (\Lambda_\sigma - \Lambda_\rho)1_{\{\tau_0 \leq \rho\}}. \]

This implies that \( \tau_0 \leq \rho \) on the \( \mathcal{F}_\sigma \)-measurable set \( \{\Lambda_\sigma - \Lambda_\rho > 0\} \). In conjunction with Lemma 6 this gives the equalities

\[ Z_{\sigma}1_{\{\Lambda_\sigma - \Lambda_\rho > 0\}} = Q\left(\{\tau_0 > \sigma\} \cap \{\Lambda_\sigma - \Lambda_\rho > 0\} \mid \mathcal{F}_\sigma\right) = 0, \quad Q \)-a.s.

But \( Q \) solves the measure extension problem, so \( Z \) is strictly positive, \( Q \)-a.s. Therefore \( Q(\Lambda_\sigma - \Lambda_\rho > 0) = 0 \), and we have finally proved our claim that \( \Lambda_\sigma - \Lambda_\rho = 0 \), \( Q \)-a.s.

Now, choose a metric \( d(\cdot, \cdot) \) on \( D \) compatible with its topology. For any subset \( A \subset D \) and any \( x \in D \), define the distance from \( x \) to \( A \) by

\[ \text{dist}(x, A) = \inf\{d(x, x') : x' \in A\}. \]

It is easy to check that \( \text{dist}(\cdot, A) \) is continuous (even Lipschitz), and in particular measurable. For each rational number \( r > 0 \) and natural number \( n > r \), define stopping times

\[ \rho_r = \begin{cases} r, & \text{if } \text{dist}(X_r, D_0) > 0 \\ \infty, & \text{otherwise}, \end{cases} \]

\[ \rho_{r,n} = n \wedge \rho_r, \]

\[ \sigma_r = n \wedge \inf\{t > \rho_{r,n} : \text{dist}(X_t, D_0) = 0\}. \]
Then the stopping times $\rho_{r,n}$ and $\sigma_{r,n}$ are all bounded, and it is a simple matter to check the inclusion
\[ \{\rho_{r,n}, \sigma_{r,n}\} \subset \{\text{dist}(X_-, D_0) > 0\}. \]
Moreover, if for some $(t, \omega)$ with $t > 0$ it holds that $\text{dist}(X_{t-}(\omega), D_0) > 0$, then by left-continuity of $X_{t-}(\omega)$ and continuity of the distance function, there is a rational $r > 0$ such that $r \leq t$ and for all $s \in [r, t]$ we have $\text{dist}(X_{s-}, D_0) > 0$. Thus for any $n > t$, we have $(t, \omega) \in \{\rho_{r,n}, \sigma_{r,n}\}$, and we deduce
\[ \bigcup_{r \in \mathbb{Q}, r > 0} \{\rho_{r,n}, \sigma_{r,n}\} = \{\text{dist}(X_-, D_0) > 0\}. \]

By the first part of the proof, $d\Lambda_t$ does not charge any of the countably many intervals in the union on the left side. It follows that $d\Lambda_t$ is supported on the set $\{\text{dist}(X_-, D_0) = 0\}$, which coincides with $\{X_- \in \overline{D_0}\}$. ■

**Remark 4** Since $h$ is continuous and $D_0 = \pi \circ h^{-1}(\{0\})$, $D_0$ is a closed set in $D$ if $\pi$ is a closed map. An example is when $\pi$ is a linear map on $\mathbb{R}^q$, and $D = \pi(\mathbb{R}^q)$. This case is discussed in Section 5.

We can now give a simple sufficient condition for $\Lambda$ to have singular paths, as in the example studied by Föllmer and Protter [9] that was mentioned in the introduction.

**Corollary 2** Assume $D$ is a subset of $\mathbb{R}^k$ for some $k$, and that the law of $X_t$ under $Q$ admits a density for almost every $t > 0$. Then, if $D_0$ is a nullset in $\mathbb{R}^k$, the paths of $\Lambda$ are singular.

**Proof.** By Fubini’s theorem, we obtain
\[ E^Q \left[ \int_0^t 1_{\{X_s \in \overline{D_0}\}} ds \right] = \int_0^t Q(\{X_s \in \overline{D_0}\}) ds = 0, \]
using that $X_s$ has a density for almost every $s$ and $\overline{D_0}$ is a nullset. Hence $\int_0^t 1_{\{X_s \in \overline{D_0}\}} ds$ zero, $Q$-a.s. Thus $\{t : X_t \in \overline{D_0}\}$ is a nullset $Q$-a.s., and it contains the support of $d\Lambda_t$ by Theorem 2. This proves the claim. ■

We finish this section with a result intended to emphasize the distinction between $\zeta$, the absorption time of the coordinate process $Y$, and the explosion time $\tau_0$ of the process $N$.

**Proposition 2** The following statements hold.

(i) Let $Q$ be any extension of $Q_0$ to all of $\mathcal{G}$. Then $\tau_0 \leq \zeta$ on $\{\tau_0 < \infty\}$, $Q$-a.s.

(ii) If $Q$ is a solution to the measure extension problem and $\tau_0 < \infty$ on $\{\zeta < \infty\}$, $Q$-a.s., then $Q(\zeta = \infty) = 1$.

**Proof.** Since the coordinate process stops at $\zeta$, it is clear that $\mathcal{G}_\infty = \mathcal{G}_\zeta$. Hence for any stopping time $\sigma$, $\mathcal{G}_\sigma = \mathcal{G}_\sigma \cap \mathcal{G}_\zeta \subset \mathcal{G}_{\sigma \wedge \zeta} \subset \mathcal{G}_\sigma$, and thus $\mathcal{G}_{\sigma \wedge \zeta} = \mathcal{G}_\sigma$. Applying this with $\sigma = t$, for any $t \geq 0$, we get
\[ M_{t \wedge \zeta} = E^Q[M_t \mid \mathcal{G}_{t \wedge \zeta}] = E^Q[M_t \mid \mathcal{G}_t] = M_t, \]
showing that $M$ is $Q$-a.s. constant after $\zeta$ (note that this holds for any martingale).

Now, on $\{\zeta < \tau_0\}$ we have $\inf_{0 \leq t \leq \zeta} M_t > 0$, and since $M$ is constant after $\zeta$ we have $\inf_{t \geq 0} M_t > 0$. Hence $\tau_0 = \infty$, and we deduce (i).

To prove (ii), first note that $X_\zeta = \pi(Y_\zeta) = \pi(\Delta) = \Delta$, and that for $t < \zeta$, $X_t \in D$ so that $X_t \neq \Delta$. The absorption time can therefore alternatively be written

$$\zeta = \inf\{t \geq 0 : X_t = \Delta\},$$

showing that $\zeta$ is in fact an $F$ stopping time. Our hypothesis says that $\tau_0 < \infty$ on $\{\zeta < \infty\}$. Hence, by part (i) above, $\tau_0 \leq \zeta$ on $\{\zeta < \infty\}$. But since Lemma 6 implies that $Z_\zeta = Q(\tau_0 > \zeta \mid F_\zeta)$ on this set, we deduce that $Z_\zeta = 0$ on $\{\zeta < \infty\}$. Now, $Q$ solves the measure extension problem, so in order to avoid a contradiction we must have $Q(\zeta = \infty) = 1$.

Remark 5

If $N$ itself is the coordinate process, then $\tau_0$ and $\zeta$ coincide, as is the case, for example, in [1]. In this case part (ii) of the above proposition implies that the measure extension problem lacks a solution for any subfiltration $F$ of the type discussed in this section. At first glance, this seems to imply that the proposition is incorrect: let, for instance, $F$ be the trivial filtration—then $P$ itself is a solution to the measure extension problem. The issue here is that the trivial filtration is not of the type introduced above, since we assumed that $\pi(\Delta) = \Delta \neq \pi(y)$ for $y \in E$. In particular, $\zeta$ is not a stopping time for the trivial filtration, and this breaks the proof of part (ii). On the other hand, part (i) remains correct even if we allow $\pi(\Delta)$ to lie in $D$, and also part (ii) remains correct as long as we additionally assume that $\zeta$ is an $F$ stopping time.

5 Solving the measure extension problem

So far we have assumed that the measure extension problem has a solution. In this section we specialize the setup from Section 4, imposing further assumptions that enable us to prove the existence of a particular solution, and to describe this solution explicitly. This is done in Section 5.1. Some examples where the main result (Theorem 3 below) applies are then discussed in Section 6.

The symbol $|\cdot|$ denotes the usual Euclidean norm, $\nabla$ is the gradient, and $\Delta$ the Laplacian (there should be confusion with the absorbing state $\Delta$.)

5.1 Linear shrinkage in a Brownian setting

We make the following assumptions, within the framework described in Section 4:

- $E = \mathbb{R}^q$, some $q \in \mathbb{N}$.
- $P$ is Wiener measure, turning the coordinate process $Y$ into $q$-dimensional Brownian motion (possibly starting from $Y_0 \neq 0$.)
• $h$ is such that $\frac{1}{h}$ is harmonic on $\mathbb{R}^q \setminus E_0$, where we define
  
  \[ E_0 = h^{-1}(\{0\}). \]

• $\pi : E \to E$ is linear, and we set $D = \pi(\mathbb{R}^q)$ and $p = \dim D = \text{rank } \pi$.

The main result is the following.

**Theorem 3** Consider the setup just described, and assume furthermore that $h$ satisfies the following conditions:

\[ t \mapsto E^P \left[ \frac{\left| \nabla \ln h(Y_t) \right|}{h(Y_t)} \right] \text{ is locally bounded on } [0, \infty), \tag{8} \]

\[ (t, x) \mapsto E^P \left[ \left| \frac{\pi(\nabla \ln h(Y_t))}{h(Y_t)} \right| \right] \text{ is locally bounded on } (0, \infty) \times D, \tag{9} \]

where the right side of (9) should be understood in the sense of regular conditional probabilities. Then the measure extension problem has a solution $Q$. It can be taken to be the measure on path space induced by the stochastic differential equation

\[ Y_t = Y_0 + W_t - \int_0^{\Lambda\wedge \tau_0} \nabla \ln h(Y_s) ds, \tag{10} \]

where $W$ is $q$-dimensional Brownian motion, and the integral is well-defined and finite, $Q$-a.s.

**Remark 6** The role of condition (8) is primarily to ensure that the optional projection of $Y$ under $Q$ can be computed in a reasonable way. Moreover, since trivially $\pi$ is a bounded operator, (8) also implies that the conditional expectation in (9) is finite for each $(t, x) \in (0, \infty) \times D$. The role of condition (9) is to ensure that $\mathcal{F}$ is small enough for the projection operation to induce sufficient smoothing. In particular, if $\mathcal{F}$ is the trivial filtration, then (9) reduces to (8).

**Remark 7** Unfortunately the assumptions of Theorem 3 are quite restrictive. While they do allow us to treat the example by Föllmer and Protter mentioned in the introduction, a major open problem for future research is to find more general conditions under which the measure extension problem can be solved.

The rest of this section is devoted to the proof of Theorem 3. The strategy can be summarized as follows: We first show that (10) indeed induces an extension $Q$ of $Q_0$. Then we describe the law of $X = \pi(Y)$ under $P$ and under $Q$. Finally, this description is used to show that the laws are locally equivalent. Since $X$ generates $\mathcal{F}$ this yields the result. We now turn to the details, which are carried out through a sequence of lemmas.

**Lemma 7** Assume that (8) is satisfied. Then the inequality

\[ \int_0^t E^{Q_0} \left[ |\nabla \ln h(Y_s)| 1_{\{s < \tau_0\}} \right] ds < \infty \tag{11} \]

holds for every $t \geq 0$. Consequently, (10) induces an extension $Q$ of $Q_0$. 14
Proof. We have
\[ E^{Q_0} \left[ |\nabla \ln h(Y_t)| 1_{\{t < \tau_0\}} \right] = E^P \left[ \frac{1}{h(Y_t)} |\nabla \ln h(Y_t)| \right]. \]

By (8), the right side is locally integrable in \( t \) on \([0, \infty)\), which implies (11). We may therefore define an \( E_\Delta \)-valued process \( W \) by
\[ W_t = Y_t - Y_0 + \int_0^{t \wedge \tau_0} \nabla \ln h(Y_s) ds, \quad t \geq 0, \]
using (11) to see that the integral on the right side is well-defined and finite. Now, for each \( n \), \( N^{\tau_0} \) is the density process of the restriction of \( Q_0 \) to \( G^{\tau_0} \) with respect to \( P \). (Recall that \( \tau_n \) is the minimum of \( n \) and the first time \( N_t \) hits level \( n \).) We observe that, by Itô's formula,
\[ N_t = \frac{1}{h(Y_t)} = 1 - \int_0^t N_s \nabla \ln h(Y_s) dY_s, \quad t < \tau_0, \]
so that an application of Girsanov's theorem yields that \( (W_t \wedge \tau_0 : t \geq 0) \) is a local martingale for each \( n \). Since \( \langle W_i, W_j \rangle \wedge \tau_0 = (t \wedge \tau_0) \delta_{ij} \), it is in fact a martingale behaving like stopped Brownian motion. A standard argument based on Doob's up- and downcrossing inequalities then shows that the limit \( \lim_{t \uparrow \tau_0} W_t \) exists in \( R^q \) on \( \{\tau_0 < \infty\} \), \( Q_0 \)-a.s. As consequence, \( Y_{\tau_0} \) also exists on \( \{\tau_0 < \infty\} \), and is different from \( \Delta \). We now simply choose the law \( Q \) so that \( Y_{\tau_0} = Y_{\tau_0}^0 \) and \( (Y_{\tau_0}^0 + t - Y_{\tau_0} : t \geq 0) \) is Brownian motion.

Lemma 8 Under \( P \), the process \( X - X_0 \) is the image of standard \( p \)-dimensional Brownian motion under the restriction of \( \pi \) to \( D \).

Proof. We have \( X - X_0 = \pi(Y - Y_0) \), the image of \( q \)-dimensional Brownian motion under the linear map \( \pi \). The restriction of \( \pi \) to \( D \) has an inverse \( \rho : D \to D \). The process \( \rho(X - X_0) \) is standard \( p \)-dimensional Brownian motion.

Lemma 9 Assume that (8) is satisfied, and let \( Q \) be the extension of \( Q_0 \) rendering (10) valid (it exists by Lemma 7). The process \( X \) can then be decomposed as
\[ X_t = X_0 + B_t + \int_0^t \theta_s ds \quad \text{for all} \quad t \geq 0, \quad Q\text{-a.s.}, \]
where \( B \) is the image of standard \( p \)-dimensional \((\mathbb{F}, Q)\) Brownian motion under the restriction of \( \pi \) to \( D \), and \( \theta_t \) satisfies, for every \( t \geq 0 \),
\[ \theta_t = E^Q \left[ \pi(\nabla \ln h(Y_t)) 1_{\{\tau_0 > t\}} \mid \mathcal{F}_t \right] \quad Q\text{-a.s.}, \quad \text{and} \quad \int_0^t E^Q [||\theta_s||] ds < \infty. \]

Proof. Due to Lemma 7, the optional projection of \( \pi(\nabla \ln h(Y_t)) 1_{\{\tau_0 > t\}} \) onto \( \mathbb{F} \) is well-defined under \( Q \). Denoting this optional projection by \( \theta \) it is clear that the given expression for \( \theta \) and the integrability statement are correct. From the definition of \( X_t \) and the linearity
of $\pi$ we obtain

$$X_t = E^Q [\pi(Y_t) \mid F_t]$$

$$= \pi(Y_0) + E^Q [\pi(W_t) \mid F_t] - E^Q \left[ \int_0^t \pi(\nabla \ln h(Y_s)) 1_{\{s<\tau_0\}} ds \mid F_t \right]$$

$$= X_0 + B_t - \int_0^t \theta_s ds,$$

where we define $B_t = E^Q [\pi(W_t) \mid F_t] + L_t$ with

$$L_t = E^Q \left[ \int_0^t \pi(\nabla \ln h(Y_s)) 1_{\{s<\tau_0\}} ds \mid F_t \right]$$

$$- \int_0^t E^Q \left[ \pi(\nabla \ln h(Y_s)) 1_{\{s<\tau_0\}} \mid F_s \right] ds.$$

Suppose we know $B$ is a (local) martingale. Since its quadratic variation coincides with that of $\pi(Y)$, $B$ is the image of some $p$-dimensional $(\mathcal{F}, Q)$ Brownian motion under the restriction of $\pi$ to $D$. To see that $B$ is indeed a martingale, first note that each component of $E^Q [\pi(W_t) \mid F_t]$ is the projection of a linear combination of martingales, hence itself a martingale. Next, we make use of the following well-known result from filtering theory (see [19], Theorem 7.12): If $\xi$ is a measurable process with $\int_0^t E^Q[|\xi_s|]ds < \infty$ for all $t \geq 0$, then

$$E^Q \left[ \int_0^t \xi_s ds \mid F_t \right] - \int_0^t E^Q [\xi_s \mid F_s] ds, \quad t \geq 0,$$

is an $(\mathcal{F}, Q)$ martingale. Applying this to each component of $L$ shows that it is a martingale. This completes the proof. ■

Lemmas 8 and 9 describe of the law of $X$ under $P$ and under $Q$. It remains to show that these laws are locally equivalent, and this is where condition 9 is crucial. A priori, 9 only asserts boundedness on compact sets bounded away from $\{0\} \times D$. The following result shows that this can be strengthened without imposing any additional assumptions. The proof uses the Moore-Penrose inverse to decompose $Y_t$ into an observable component and an independent component.

**Lemma 10** Assume condition 9 is satisfied. Then there is some $\varepsilon > 0$, and an open set $O \subset D$ containing $X_0$, such that the function in 9 is bounded on $(0, \varepsilon) \times O$.

**Proof.** Define $G(y) = h(y)^{-1} |\pi(\nabla \ln h(y))|$, and let $\pi^+$ be the Moore-Penrose inverse of the linear map $\pi$. Since $\pi^+$ is invertible on $D$ (its inverse is $\pi$), the function in 9 can be written

$$E^P \left[ G(Y_t) \mid \pi(Y_t) = x \right] = E^P \left[ G(Y_t) \mid U_t = \pi^+(x) \right],$$

where we set $U_t = \pi^+ \pi(Y_t)$. Now decompose $Y_t$ as

$$Y_t = \pi^+ \pi(Y_t) + (\text{Id} - \pi^+ \pi)(Y_t) = U_t + V_t$$

($V_t$ is defined by this relation), and note that

$$\pi^+ (\text{Id} - \pi^+ \pi) = \pi^+ \pi - \pi^+ \pi \pi^+ \pi = \pi^+ \pi - \pi^+ \pi = 0$$
by basic properties of the Moore-Penrose inverse. Hence $Y_t = U_t + V_t$ is the decomposition of $Y_t$ as a direct sum in $D \oplus D^\perp$. In particular $U_t$ and $V_t$ are independent, so

$$E^P \left[ G(Y_t) \mid U_t = \pi^+(x) \right] = E^P \left[ G(u + V_t) \right]_{u = \pi^+(x)}.$$

We now focus on bounding $E^P[G(z + V_t)]$. The random variable $V_t$ concentrates on $D^\perp$ and is nondegenerate Normal there, so it has a density with respect to Lebesgue measure on $D^\perp$ given by

$$f_t(v) = \frac{1}{(2\pi t)^{m/2} |\det \Sigma|^{1/2}} \exp \left( -\frac{1}{2t} (v - V_0)^\top \Sigma^{-1} (v - V_0) \right), \quad v \in D^\perp.$$

Here $m = q - p = \dim D^\perp$ and, by a slight abuse of notation, $\Sigma^{-1}$ the inverse on $D^\perp$ of the covariance operator of $V_t$, with $\det \Sigma$ being its determinant.

Now, let $\varepsilon > 0$ be a number to be determined later. We let $B = \{u \in D : |u - U_0| < \varepsilon\}$ be the ball in $D$ of radius $\varepsilon$ centered at $U_0$, and $E$ be the ellipsoid in $D^\perp$ given by

$$E = \left\{ v \in D^\perp : \frac{1}{m} (v - V_0)^\top \Sigma^{-1} (v - V_0) < \varepsilon \right\}.$$

The following can be verified by direct differentiation:

**Claim:** Fix $\alpha > 0$ and $\beta > 0$, and let $\psi(t) = t^{-\alpha/2} \exp(-t^{-1}\beta/2)$. Then $\psi$ is nondecreasing on the interval $[0, \beta/\alpha]$.

The Claim shows that whenever $v \notin E$, $f_t(v)$ decreases as $t$ decreases. This gives us the following bound for any $t \in (0, \varepsilon]$:

$$E \left[ G(z + V_t) \right] = \int_E G(u + v) f_t(v) dv + \int_{D^\perp \setminus E} G(u + v) f_t(v) dv$$

$$\leq \sup_{v \in E} G(u + v) + \int_{D^\perp \setminus E} G(u + v) f_\varepsilon(v) dv$$

$$\leq \sup_{v \in E} G(u + v) + E^P \left[ G(z + V_\varepsilon) \right].$$

Therefore

$$\sup_{(t, u) \in (0, \varepsilon) \times B} E \left[ G(u + V_t) \right] \leq \sup_{y \in B \oplus E} G(y) + \sup_{u \in B} E^P \left[ G(u + V_\varepsilon) \right].$$

By smoothness of $h$ outside $E_0$ and the fact that $h(Y_0) = 1$, it is possible to choose $\varepsilon > 0$ small enough that the set $B \oplus E$, which is a neighborhood of $Y_0$, is bounded away from $E_0$. With such an $\varepsilon$, the first term on the right side above is finite. The second term is also finite due to the local boundedness assumption (9). Setting $O = \pi(B)$, which is again open in $D$, gives the statement of the lemma.

The same orthogonal decomposition of $Y_t$ as in the proof of Lemma 10 gives the following unsurprising result.
Lemma 11  Consider a nonnegative measurable function \( G : \mathbb{E} \to \mathbb{R}_+ \). The equality
\[
E^P [G(Y_t) \mid \mathcal{F}_t] = E^P [G(Y_t) \mid \pi(Y_t) = x]_{x=X_t}
\]
holds \( P \)-a.s. for all \( t \geq 0 \).

Proof. With the notation from the proof of Lemma 10 we get, \( P \)-a.s.,
\[
E^P [G(Y_t) \mid \mathcal{F}_t] = E^P [G(Y_t) \mid X_s : s \leq t] = E^P [G(U_t + V_t) \mid U_s : s \leq t] = E^P [G(u + V_t)_{u=U_t}] = E^P [G(\pi^+(x) + V_t)]_{x=X_t}.
\]

By means of an analogous calculation, the right side is also seen to be equal to \( E^P [G(Y_t) \mid \pi(Y_s) = x]_{x=X_s} \).

The following simple refinement of Bayes’ rule is useful for dealing with non-equivalent measures.

Lemma 12  Suppose \( R_1 \ll R_2 \) are two probability measures with Radon-Nikodym derivative \( Z = \frac{dR_1}{dR_2} \), and let \( X \) be a random variable in \( L^1(R_1) \). Let \( \mathcal{H} \) be a sub-\( \sigma \)-field and suppose \( A \in \mathcal{H} \) satisfies \( A \subset \{ E^{R_2}[Z \mid \mathcal{H}] > 0 \} \). Then \( E^{R_1}[X \mid \mathcal{H}] \) is uniquely defined on \( A \) up to an \( R_2 \)-nullset, and we have
\[
E^{R_2}[Z \mid \mathcal{H}] E^{R_1}[X \mid \mathcal{H}] 1_A = E^{R_2}[ZX 1_A \mid \mathcal{H}]
\]
\( R_2 \)-a.s. (and hence \( R_1 \)-a.s.)

Proof. To prove the first statement, let \( Y \) and \( Y' \) be two versions of \( E^{R_1}[X \mid \mathcal{H}] \). Then \( R_1(Y \neq Y') = 0 \), and we get
\[
0 = R_1(\{ Y \neq Y' \} \cap A) = E^{R_2}[E^{R_2}[Z \mid \mathcal{H}] 1_{\{ Y \neq Y' \} \cap A}].
\]

Since \( E^{R_2}[Z \mid \mathcal{H}] > 0 \) on \( A \), we get \( R_2(\{ Y \neq Y' \} \cap A) = 0 \), as desired. The second statement follows from the following calculation, where \( B \in \mathcal{H} \) is arbitrary:
\[
E^{R_2}[E^{R_2}[Z \mid \mathcal{H}] E^{R_1}[X \mid \mathcal{H}] 1_{A \cap B}] = E^{R_2}[ZE^{R_1}[X \mid \mathcal{H}] 1_{A \cap B}] = E^{R_1}[X 1_{A \cap B}] = E^{R_2}[ZX 1_{A \cap B}].
\]

The next lemma is the key to proving that the laws of \( X \) under \( P \) and \( Q \) are equivalent. It relies on the strengthening of condition (9) given in Lemma 9.

Lemma 13  Assume that (8) and (9) are satisfied, and let \( \theta \) and \( Q \) be as in Lemma 9. For each \( t \geq 0 \), we have
\[
\int_0^t |\theta_s|^2 ds < \infty \quad Q \text{-a.s.}
\]

18
Furthermore, the local boundedness condition (9) implies that
where the equality follows from Lemma 4. Then
\[ \tau \]

Therefore, by Lemma 11, the equality

\[ \text{which is finite by Lemma 9. Since also } E[M_t | F_t] > 0 \text{ on } \{\sigma_0 > t\}, \]

we may apply Lemma 12 with \( R = P \) and \( R_2 = Q \) to get, Q-a.s.,

\[ \theta_t = E^Q \left[ \pi(\nabla \ln h(Y_t)) \left( \tau_{t_0 > t} \land \{\sigma_0 \leq t\} \right) \big| F_t \right] \quad \theta_t = E^P \left[ h(Y_{t_0}) \left( \tau_{t_0 > t} \land \{\sigma_0 \leq t\} \right) \big| F_t \right] \]

Now, since \( E^Q[M_t | F_t] \) is a finite, càdlàg process, it is pathwise bounded on each \([0, t]\)
(with the bound depending on \( t \) and \( \omega \) in a possibly non-predictable way.) It thus suffices to prove that \( \int_0^{\tau_{t_0 \land \sigma_0}} |\xi_s|^2 ds < \infty \), Q-a.s., where \( \xi_s = E^P[h(Y_s)^{-1} \pi(\nabla \ln h(Y_s)) | F_s] \). By Lemma 12 this conditional expectation is uniquely defined \( P \)- and Q-a.s. on \( \{s < \sigma_0\} \).

Therefore, by Lemma 11 the equality

\[ \xi_s = E^P \left[ \frac{1}{h(Y_s)} \pi(\nabla \ln h(Y_s)) \big| \pi(Y_s) = x \right]_{x=X_s} \]

holds Q-a.s. on \( \{s < \sigma_0\} \).

Now, let \( O \subset D \) and \( \varepsilon > 0 \) be the objects obtained from Lemma 10 and define

\[ \rho = \inf \{0 \leq t \leq \varepsilon \land \sigma_0 : X_t \notin O\}. \]

Since \( O \) is open and contains \( X_0 \), we have \( \rho > 0 \), Q-a.s. (Note that \( \sigma_0 > 0 \) by right continuity of \( E^Q[M_t | F_t] \).) The properties of \( O \) and \( \varepsilon \) imply that \( \xi_s \) is bounded on \((0, \rho)\).

Furthermore, the local boundedness condition (9) implies that \( \xi_s \) is pathwise bounded on \([\rho, t \land \sigma_0]\) (again with a random bound). It follows that \( \xi \) is square integrable on \((0, t \land \sigma_0)\), which is what we had to show. The proof of the lemma is now complete. \( \blacksquare \)

**Proof of Theorem 8.** We need to prove that \( Q \) and \( P \) are equivalent on each \( F_t \). By Lemmas 8 and 13 we can define a strictly positive \((\mathbb{F}, Q)\) local martingale \( Z \) via

\[ Z_t = \exp \left( \int_0^t \theta_s^\top dB_s - \frac{1}{2} \int_0^t |\theta_s|^2 ds \right), \quad t \geq 0. \]

Consequently, since \( \mathbb{F} \) is a standard system, we can find the Föllmer measure associated with \( Z \). To be precise, define stopping times

\[ \rho_n = \inf \{t \geq 0 : Z_t \geq n\}, \quad \rho_0 = \lim_{n \to \infty} \rho_n. \]
Then there is a unique probability $R_0$ on $\mathcal{F}_{\rho_n}$ such that $\frac{dQ}{dR_0}{\mid}_{\rho_n} = \frac{1}{2\rho_n}$ for each $n$. Girsanov’s theorem and Lévy’s characterization of Brownian motion then imply that the process

$$X_{t\wedge \rho_n} - X_0 = B_{t\wedge \rho_n} - \int_0^{t\wedge \rho_n} \theta_s ds, \quad t \geq 0,$$

is Brownian motion (with some invertible volatility matrix) stopped at $\rho_n$. Moreover, since $X$ generates the filtration $\mathcal{F}$, $\rho_n$ only depends on the path of $X$. Therefore the law of $(X_{t\wedge \tau_n} : t \geq 0)$ under $R_0$ is the same as its law under $P$. Consequently, since

$$\int_0^t \theta_s^2 ds < \infty$$

for all $t \geq 0$, $P$-a.s., so that $P(\rho_0 = \infty) = 1$, we also have $R_0(\rho_0 = \infty) = 1$. It follows that $X - X_0$ (not stopped this time) is Brownian motion under $R_0$, and we deduce that $R_0 = P$ on each $\mathcal{F}_t$. This leads to the domination relations

$$P\mid_{\mathcal{F}_t} \ll Q\mid_{\mathcal{F}_t} \ll R_0\mid_{\mathcal{F}_t} = P\mid_{\mathcal{F}_t},$$

which proves the theorem. ■

6 Examples

In this section we discuss some examples where the conditions of Theorem 3 can be verified explicitly. We also give one recipe for how new examples can be constructed from old ones.

Example 1 (The inverse Bessel process) Let $E = \mathbb{R}^3$, and suppose $Y_0 = (1, 0, 0)$. Take $h(y) = |y|$. Then $1/h$ is harmonic on $\mathbb{R}^3 \setminus \{0\}$, and $N$ is the reciprocal of a BES(3) process. In particular it is a strict local martingale. To specify the smaller filtration we let $\pi$ be projection onto the first coordinate of $\mathbb{R}^3$. This puts us exactly in the example analyzed by Föllmer and Protter [9], mentioned in the introduction.

Let us verify the conditions (8) and (9) of Theorem 3. First, note that

$$\nabla h(y) = y|y|^{-1},$$

so that

$$E^P \left[ \frac{1}{h(Y_t)} |\nabla \ln h(Y_t)| \right] = E^P \left[ \frac{1}{h(Y_t)^2} \right] = E^P \left[ N_t^2 \right].$$

The well-known fact that $t \mapsto E^P[N_t^2]$ is bounded (see Chapter 1.10 in [3]) directly implies (8). To prove (9), write

$$F(t, x) = E^P \left[ \frac{1}{h(Y_t)} \pi(\nabla \ln h(Y_t)) \bigg | \pi(Y_t) = x \right] = E^P \left[ \frac{Y_1^1}{|Y_t|^3} \bigg | Y_1^1 = x \right]$$

$$= E^P \left[ \frac{x}{x^2 + (Y_t^2)^2 + (Y_3^3)^2} \right],$$

where the last equality follows from the independence of the components of $Y$. By the scaling property of Brownian motion, $F(t, x) = t^{-1}F(1, t^{-1/2}x)$. To prove local boundedness of $F$ on $(0, \infty) \times \mathbb{R}$ it is therefore enough to show that $x \mapsto F(1, x)$ is locally bounded.
on \( \mathbb{R} \). Noting that the random variable 
\[
Z = (Y_1^2)^2 + (Y_3^3)^2
\]
is \( \chi^2_2 \) distributed, we obtain
\[
|F(1, x)| \leq E^P \left[ \frac{|x|}{(x^2 + Z)^{3/2}} \right] 
\leq \frac{|x|}{2} \int_0^\infty (x^2 + z)^{-3/2} e^{-z/2} dz
\leq \frac{|x|}{2} \int_0^\infty (x^2 + z)^{-3/2} dz = \frac{1}{2}.
\]

We thus obtain (9), as required.

To connect this example with the theory developed in the previous sections, note that the set
\[
D_0 = \pi \circ h^{-1}(\{0\})
\]
is simply equal to \( \{0\} \subset \mathbb{R} \). Theorem 2 then tells us that the process \( \Lambda \) only increases on the set \( \{t : Y_t^1 = 0\} \). In view of Proposition 1 this explains the appearance of the local time in the expression for \( E^P[N_t \mid F_t] \) found by Föllmer and Protter—see (1) in the introduction.

**Example 2 (The inverse Bessel process embedded in \( \mathbb{R}^4 \))** We now consider what happens when the previous example is embedded in \( \mathbb{R}^4 \). Thus, we set \( E = \mathbb{R}^4 \) and let \( Y \) start from \((1, 0, 0, 0)\). The function \( h \) is now given by
\[
h(y) = |\overline{y}|,
\]
where \( \overline{y} = (y_1, y_2, y_3) \).

In other words, \( h(y) \) is the distance between \( y \) and the \( y_4 \)-axis. Then \( N_t = \frac{1}{h(Y_t)} \) is again the reciprocal of a \( \text{BES}(3) \) process, and again a strict local martingale. It is clear that \( 1/h \) is harmonic outside the \( y_4 \)-axis, \( E_0 = \{y : \overline{y} = 0\} \). We let \( \pi \) be given by the following matrix representation in the canonical basis on \( \mathbb{R}^4 \):
\[
\pi(y) = Ay,
\]
where \( A = \begin{pmatrix} 1 & 0 & 0 & \alpha_1 \\ 0 & 1 & 0 & \alpha_2 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \) for some \( \alpha_1, \alpha_2 \in \mathbb{R} \setminus \{0\} \).

Note that \( D = \pi(E) \) can be identified with \( \mathbb{R}^2 \). We proceed to verify conditions (8) and (9). First, the gradient of \( h \) is given by
\[
\nabla h(y) = \left( \frac{\overline{y}}{|\overline{y}|}, 0 \right) \in \mathbb{R}^4.
\]

Hence
\[
E^P \left[ \frac{1}{h(Y_t)} \nabla \ln h(Y_t) \right] = E^P \left[ N_t^2 \right],
\]
and we get (8) as in the previous example. We continue with (9), and define
\[
F(t, x) = \begin{pmatrix} F_1(t, x) \\ F_2(t, x) \end{pmatrix} = E^P \left[ \frac{1}{h(Y_t)} \pi(\nabla \ln h(Y_t)) \mid \pi(Y_t) = x \right].
\]
Using the definition of $h$, the expression for $\nabla h$, and the definition of $\pi$, one gets

$$F_i(t, x) = E^P \left[ \frac{Y_i^t}{Y_i^1} \bigg| \pi(Y_i) = x \right], \quad i = 1, 2.$$  

The Brownian scaling property again shows that $F(t, x) = t^{-1} F(1, t^{-1/2} x)$, so just as in the previous example we need only consider $F(1, x)$. Next,

$$|F_i(1, x)| \leq E^P \left[ \frac{|Y_i|^1}{[(Y_i^1)^2 + (Y_i^3)^2]^{3/2}} \bigg| \pi(Y_1) = x \right]. \quad (12)$$

To continue, we need to know the distribution of $(Y_1^1, Y_1^3)$ conditionally on $\pi(Y_1) = x$, for $i = 1, 2$. This can for instance be done using the formula for the conditional multivariate Normal, applied to the multivariate Normal vector $(Y_1^1, Y_1^3, \pi(Y_1))$. The result of this calculation is that $Y_1^1$ and $Y_1^3$ are conditionally independent, with $Y_1^3$ having mean zero and unit variance, and $Y_1^i$, $i = 1, 2$, satisfying

$$\mu_1 = E[Y_1^1 \mid \pi(Y_1) = x] = 1 + \frac{(\alpha_2^2 + 1)(x_1 - 1) - \alpha_1 \alpha_2 x_2}{1 + \alpha_1^2 + \alpha_2^2}$$
$$\mu_2 = E[Y_1^2 \mid \pi(Y_1) = x] = 1 + \frac{(\alpha_1^2 + 1)x_2 - \alpha_1 \alpha_2 (x_1 - 1)}{1 + \alpha_1^2 + \alpha_2^2}$$
$$\sigma_1^2 = \text{Var}[Y_1^i \mid \pi(Y_1) = x] = \frac{\alpha_i^2}{1 + \alpha_1^2 + \alpha_2^2}.$$  

Continuing from (12) and using that $\alpha_1$ and $\alpha_2$ are nonzero,

$$|F_i(1, x)| \leq \frac{1}{2\pi \sigma_i} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{|u|}{(u^2 + v^2)^{3/2}} \exp \left( -\frac{(u - \mu_i)^2}{2\sigma_i^2} - \frac{v^2}{2} \right) dudv.$$  

Now split the inner integral (with variable $u$) into two parts: the first over $(-1, 1)$ and the second over $\mathbb{R} \setminus (-1, 1)$. Starting with the first part, we get

$$\frac{1}{2\pi \sigma_i} \int_{-\infty}^{\infty} \int_{-1}^{1} \frac{|u|}{(u^2 + v^2)^{3/2}} \exp \left( -\frac{(u - \mu_i)^2}{2\sigma_i^2} - \frac{v^2}{2} \right) dudv$$
$$\leq \frac{1}{2\pi \sigma_i} \int_{-\infty}^{\infty} \int_{-1}^{1} \frac{|u|}{(u^2 + v^2)^{3/2}} du e^{-v^2/2} dv$$
$$= \frac{1}{\pi \sigma_i} \int_{-\infty}^{\infty} \left( \sqrt{1 + v^2} - \sqrt{v^2} \right) e^{-v^2/2} dv$$
$$\leq \sqrt{\frac{2}{\pi \sigma_i}},$$

where the last line used the inequality $\sqrt{a^2 + b^2} \leq |a| + |b|$ and then the fact that the Normal density integrates to one. We now consider the integral over the complementary
set $\mathbb{R} \setminus (-1,1)$. Since $u^2 \geq 1$ there, we get

$$\frac{1}{2\pi\sigma_i} \int_{-\infty}^{\infty} \int_{\mathbb{R} \setminus (-1,1)} \frac{|u|}{(u^2 + v^2)^{3/2}} \exp \left( -\frac{(u - \mu_i)^2}{2\sigma_i^2} - \frac{v^2}{2} \right) \, du \, dv$$

$$\leq \frac{1}{2\pi\sigma_i} \int_{-\infty}^{\infty} \int_{\mathbb{R} \setminus (-1,1)} |u| \exp \left( -\frac{(u - \mu_i)^2}{2\sigma_i^2} - \frac{v^2}{2} \right) \, du \, dv$$

$$\leq E^P \left[ |\pi(Y_1)| \mid \pi(Y_1) = x \right].$$

The right side is the expectation of a folded Normal distribution, and its value is a smooth function of $\mu_i$ (see [18] or compute directly.) Consequently it is a locally bounded function of $x$, and this finally shows that (9) holds.

Finally, note that $D_0 = \pi(E_0) = \{ (\lambda\alpha_1, \lambda\alpha_2) : \lambda \in \mathbb{R} \}$. This is a proper subspace in $D = \mathbb{R}^2$, and in particular it is Lebesgue-null. We would therefore expect that the semimartingale decomposition of the projection of $N$ onto $\mathbb{F}$ in this case also has a singular component.

**Example 3 (A counterexample)** Consider again the situation in Example 2, but this time set $\alpha_1 = \alpha_2 = 0$. Then $Y^4$ does not play any role at all, and $\mathbb{F}$ is generated by $(Y^1, Y^2)$. In this case the measure extension problem has no solution—indeed, this corresponds to projecting the inverse Bessel process onto the filtration $\mathbb{F}^{1,2}$ mentioned in the introduction, and according to Föllmer and Protter’s results (Theorem 5.2 in [9]) this projection is again a local martingale. Corollary 1 then shows that no solution to the measure extension problem can be found. Condition (9) can therefore not be satisfied, and this can indeed be verified directly: with $F_i(t, x)$ as in Example 2, we have

$$|F_i(1, x)| = E^P \left[ \frac{|x_i|}{(x_1^2 + x_2^2 + (Y_1^3)^2)^{3/2}} \right]$$

$$\geq \frac{1}{\sqrt{2\pi e}} \int_{-1}^{1} \frac{|x_i|}{(x_1^2 + x_2^2 + u^2)^{3/2}} \, du$$

$$= \frac{2}{\sqrt{\pi e}} \left( \frac{|x_i|}{(x_1^2 + x_2^2)^{3/2}} \right) \sqrt{1 + x_1^2 + x_2^2}.$$}

The right side is unbounded near the origin.

**Example 4 (Building new examples from old)** Suppose we have functions $h_1, \ldots, h_m$ such that for each $i$, $1/h_i$ is harmonic outside $h_i^{-1}(\{0\})$. We define the set

$$E_0 = \bigcup_{i=1}^{m} h_i^{-1}(\{0\})$$

as the collection of points where some $h_i$ vanishes. We may then define $h$ by

$$\frac{1}{h} = \frac{1}{h_1} + \cdots + \frac{1}{h_m} \quad \text{on } E \setminus E_0,$$

where $E_0$ is the collection of points where some $h_i$ vanishes. Then $h$ is a new example of a function that satisfies the conditions of the theorem. 

---

23
and extend it continuously to all of $E$ by setting $h(y) = 0$, $y \in E_0$. We have the following result.

**Lemma 14** Consider $h$ and $E_0$ as above. The function $1/h$ is harmonic outside $E_0$ and we have

$$\frac{1}{h} \nabla \ln h = \frac{1}{h_1} \nabla \ln h_1 + \cdots + \frac{1}{h_m} \nabla \ln h_m.$$ 

**Proof.** By linearity of the Laplacian it is clear that $1/h$ is harmonic. The second statement follows from the following elementary calculation.

$$\nabla h = -\left( \frac{1}{h_1} + \cdots + \frac{1}{h_m} \right)^{-2} \left( \nabla \left( \frac{1}{h_1} \right) + \cdots + \nabla \left( \frac{1}{h_m} \right) \right)$$

$$= h^2 \left( \frac{1}{h_1} \nabla \ln h_1 + \cdots + \frac{1}{h_m} \nabla \ln h_m \right).$$

It follows directly from this lemma that if each $h_i$ satisfies (8) and (9), then the same will be true for $h$. A simple application of this result is that any process $N$ of the form

$$N_t = \frac{1}{|Y_t - y^{(1)}|} + \cdots + \frac{1}{|Y_t - y^{(m)}|},$$

where $y^{(1)}, \ldots, y^{(m)} \in \mathbb{R}^3$ are fixed and different from $Y_0$, induces a Föllmer measure that can be extended to an equivalent measure on the subfiltration generated by $Y^1$.
