ABSTRACT

We present the discovery of a candidate of giant radio-quiet Lyα blob (RQLAB) in a large-scale structure around a high-redshift radio galaxy (HzRG) lying in a giant Lyα halo, B3 J2330+3927 at redshift $z = 3.087$. We obtained narrow- and broad-band imaging around B3 J2330+3927 with Subaru/Suprime-Cam to search for Lyα emitters (LAEs) and absorbers (LAAs) at redshift $z = 3.09 \pm 0.03$. We detected candidate 127 LAEs and 26 LAAs in the field of view of 31′ × 24′ (58 × 44 comoving Mpc). We found that B3 J2330+3927 is surrounded by a 130 kpc Lyα halo and a large-scale (~ 60 × 20 comoving Mpc) filamentary structure. The large-scale structure contains one prominent local density peak with an overdensity of greater than 5, which is 8′ (15 comoving Mpc) away from B3 J2330+3927. In this peak, we discovered a candidate 100 kpc RQLAB. The existence of both types of Lyα nebulae in the same large-scale structure suggests that giant Lyα nebulae need special large-scale environments to form. On smaller scales, however, the location of B3 J2330+3927 is not a significant local density peak in this structure, in contrast to the RQLAB. There are two possible interpretations of the difference of the local environments of these two Lyα nebulae. Firstly, RQLAB may need a prominent ($\delta \sim 5$) density peak of galaxies to form through intense star-bursts due to frequent galaxy interactions/mergers and/or continuous gas accretion in an overdense environment. On the other hand, Lyα halo around HzRG may not always need a prominent density peak to form if the surrounding Lyα halo is mainly powered by its radio and AGN activities. Alternatively, both RQLAB and Lyα halo around HzRG may need prominent density peaks to form but we could not completely trace the density of galaxies because we missed evolved and dusty galaxies in this survey.

Key words: galaxies: evolution – galaxies: formation – galaxies: individual: B3 J2330+3927 – cosmology: observations.

1 INTRODUCTION

Lyα blobs (LABs) are large Lyα nebulae in the high redshift Universe. Since the 1980’s, LABs have been discov-
erated around high-redshift radio galaxies (HzRGs, McCarthy 1993; Miley & De Breuck 2002). As the size and luminosity of these radio-loud LABs (RLLAB) show correlation with their radio activities, the formation mechanisms of LABs are thought to be mainly related to their radio and AGN activities (van Ojik et al. 1997). However, the formation mechanisms of the diffuse outer parts of the nebulae may be different from those of the bright central part related to AGN activities, since the outer parts of the nebulae show more quiescent kinematics than the central part and show more varied structures, such as filaments and bubbles (Villar-Martín et al. 2003; Reuland et al. 2003). Since the 2000’s, LABs lacking strong radio sources or AGN have been discovered (radio-quiet LAB, or RQLAB, Steidel et al. 2001). RQLABs also show filamentary and bubble-like structures, and the morphology of the outer parts of RLLABs and RQLABs are very similar (Matsuda et al. 2004). Although at least three possible ideas, such as cold gas accretion, galactic winds, and photoionization by intense star-bursts or by obscured AGN, have been proposed to explain the formation mechanisms of the RQLABs (Tanguchi & Shioya 2000; Haiman, Spaans, & Quataert 2000; Chapman et al. 2001), there is no consensus yet (Geach et al. 2009; Dijkstra & Loeb 2009). Both RLLABs and RQLABs have bright sub-millimeter (sub-mm) sources and related objects, but this relation is still unclear. 

While giant LABs are very rare objects, protoclusters and the surrounding large-scale structures often contain multiple giant LABs. The number densities of 100 kpc-scale LABs have been estimated to be $< 3 \times 10^{-7} \text{ Mpc}^{-3}$ from several blind surveys for LABs (Saito et al. 2003; Smith & Jarvis 2007; Yang et al. 2009). Despite this rarity, the SSA22 protocluster at $z = 3.09$ contains two to three hundred kiloparsec RQLABs with a spatial separation of $\sim 6$ megaparsec (Steidel et al. 2004; Smail et al. 2005; Venemans et al. 2005). It is possible that RQLABs and RQLABs are related to giant LABs, but this relation is still unclear.

Table 1. Summary of Observations

| Filter | $\lambda_{\text{cent}}/\Delta\lambda$ | Exposure Time | 5\$ (lim)$^b$ | FWHM |
|-------|--------------------------------|---------------|-----------|-----|
| N8497 | 4977/77 | 14400 ($1800 \times 8$) | 25.6 | 0.7-0.9 |
| B     | 4417/807 | 2880 ($360 \times 8$) | 26.5 | 0.5-0.9 |
| V     | 5447/935 | 4320 ($360 \times 12$) | 26.4 | 0.6-0.7 |
| BV    | 4977/1742 | – | 26.6 | 1.0 |

$^a$The central wavelength and FWHM of the filters.

$^b$The 5$\sigma$ limiting magnitudes within 2$''$ diameter apertures.
size parameter of 64 pixels (13’’) before combining the images. We have confirmed that our results are not sensitive to these choices (see Section 3). Photometric calibration was obtained from the spectroscopic standard stars, LDS749B, and G191-B2B (Oke 1990). The magnitudes were corrected for Galactic extinction of \( E(B - V) \) = 0.124 mag (Schlegel, Finkbeiner, & Davis 1998). The variation of the extinction in this field is small (peak to peak, \( \pm 0.007 \) mag) and thus it does not affect our results.

The combined images were aligned and smoothed with Gaussian kernels to match their seeing to a FWHM of 1’’/0. We made a \( BV \) image \( [BV = (2B + V)]/3 \) for the continuum at the same effective wavelength as \( NB497 \). The total size of the field analyzed here is 31’’.2 \times 23’’.6 after removal of low S/N regions near the edges of the images. We also masked out the halos of the bright stars. The resultant total effective area is 699 arcmin\(^2\) (corresponding to a comoving volume of \( 1.6 \times 10^3 \) Mpc\(^3\) at \( z = 3.1 \).)

Object detection and photometry were performed using SExtractor version 2.5.0 (Bertin & Arnouts 1996). The object detections were made on the \( NB497 \) image (for Ly\( \alpha \) emitters, or LAEs) and \( BV \) image (for Ly\( \alpha \) absorbers, or LAAs), using a Gaussian detection kernel with FWHM of 1’’. We detected objects that had 5 connected pixels above \( 5 \)σ of the sky background rms noise. The magnitudes and colours are measured for each object in 2’’ diameter apertures.

3 RESULTS

Fig. 2(a) shows a colour-magnitude plot for the \( NB497 \) detected objects. We selected 127 candidates as LAEs with the following criteria; (1) \( NB497 < 25.6 \) mag (5 \( \sigma \)), (2) \( BV - NB497 > 0.75 \) mag \( (EW_{obs} > 80 \) Å\)), (3) \( \Sigma > 3.5 \), where the \( \Sigma \) is the ratio between the \( NB497 \) excess and the uncertainty of \( BV - NB497 \) colour based on photometric errors of both \( BV \) and \( NB497 \) for objects with constant \( f_v \) spectra. The Ly\( \alpha \) luminosity limit of our LAA sample is \( 1.3 \times 10^{42} \) erg s\(^{-1}\). We note that the contamination of [OII]\( \lambda 3727 \) emitters at \( z = 0.33 \) in our LAA sample should be negligible thanks to the observed equivalent width limit of 80 Å (< 2%, e.g., Gawiser et al. 2007).

We verified that the entire field of view of the B3 J2330+3927 field has overdensity compared with blank fields or not, using the \( NB497 \) image of Subaru-XMM Deep survey (SXDS) field taken by Hayashino et al. (2004). As a result, the number density of LAEs in the B3 J2330+3927 field is similar to that in SXDS at least for a sub-sample of bright LAE candidates with a large EW (L(Ly\( \alpha \)) > 1.7 \times 10^{42} \) erg s\(^{-1}\) and \( EW_{obs} > 120 \) Å). Thus the B3 J2330+3927 field does not show evidence for overdensity in the entire field of view.

Fig. 2(b) shows a colour-magnitude plot for the \( BV \) detected objects. We selected 26 candidates as LAAs with the following criteria; (1) \( BV < 25.6 \) mag (12.5 \( \sigma \)), (2) \( BV - NB497 < 0.7 \) mag \( (EW_{obs} < 40 \) Å\)), (3) \( \Sigma > 3.5 \), where the \( \Sigma \) is the ratio between the \( NB497 \) depress and the uncertainty of \( BV - NB497 \) colour. We used the same equivalent width limit for LAAs as used in Steidel et al. (2000). They have spectroscopically confirmed that their LAA sample is at \( z = 3.1 \) (Steidel et al. 2000).

Fig. 3 shows the spatial distribution of candidate 127 LAEs and 26 LAAs in this field and the smoothed density map of these objects. We note that neither LAE nor LAA is detected at the positions of two sub-mm sources around B3 J2330+3927 in Stevens et al. (2003). We made the density map smoothed with a Gaussian kernel of \( \sigma = 1’’/0 \), or FWHM = 4.4 comoving Mpc. The smoothing kernel size was chosen to match the median distance between the nearest neighbours in this sample.

We defined high-density regions (HDRs) as the regions with the overdensity \( \delta \equiv (n - \bar{n})/\bar{n} > 0 \). We mark the position of B3 J2330+3927 and the approximate direction of the radio axis (Pérez-Torres & De Breuck 2003). B3 J2330+3927 is surrounded by a large HDR with an extent of \( \sim 30’ \times 10’’ \) (\( \sim 60 \times 20 \) comoving Mpc). We have confirmed that it is difficult to reproduce such large HDRs from random distribution. We generated 10,000 density maps with the same size with 153 randomly distributed sources. The probability of finding HDRs with an area equal to or larger than that found around the B3 J2330+3927 is less than
0.4%. Thus the large HDR around B3 J2330+3927 should be a real large-scale structure.

This large-scale structure contains one prominent density peak centred at \((\alpha, \delta) = 23:29:53.5, +39:21:45\) (J2000.0), which is \(8'\) (15 comoving Mpc) south-west from B3 J2330+3927. This peak has an overdensity of \(\delta \sim 5.5\), which is greater than a significance level of 6 \(\sigma\) compared with the average of the density fluctuation in this map. Moreover we discovered a candidate giant RQLAB lying very close to the density peak. However, the location of B3 J2330+3927 is not a significant local density peak in this structure, in contrast to the new RQLAB. We note that there is no evidence for an overdensity of LAAs in the density peak, although LAEs appear to have a similar spatial distribution to LAAs on large scales in this field. We have confirmed that the results do not change significantly if we use different \(NB_{497}\) flat-field images taken by other projects and apply slightly different selection criteria for LAEs and LAAs.

Fig. 4 shows \(B, NB_{497}, V\) colour images of the candidate RQLAB, LAB2330+3922 and B3 J2330+3927. The RQLAB has an extent of 13'' (100 kpc) and it is one of the largest LABs known to date. The RQLAB has two Ly\(\alpha\) peaks and was initially detected as two different LAEs. B3 J2330+3927 also has giant Ly\(\alpha\) nebula with an extent of 17'' (130 kpc). We listed the properties of these two LABs in Table 2. The Ly\(\alpha\) luminosities and observed Ly\(\alpha\) equivalent widths are measured using isophotal apertures with a threshold of \(2 \times 10^{-18}\) erg s\(^{-1}\) cm\(^{-2}\) arcsec\(^{-2}\) (the lowest contours in Fig. 4). We have confirmed that there is no other prominent LAB in this field except for these two LABs, searching for LABs with the detection threshold of \(2 \times 10^{-18}\) erg s\(^{-1}\) cm\(^{-2}\) arcsec\(^{-2}\) and the selection criteria of \(BV - NB_{497} \geq 1.5\) mag, \(NB_{497} \leq 25\) mag, isophotal area \(\geq 50\) arcsec\(^2\). We have also confirmed that the results
do not change significantly if we use different mesh sizes for sky-subtraction in the data reduction process.

4 DISCUSSION AND CONCLUSIONS

We discovered a new candidate 100 kpc RQLAB, which appears to lie in the same large-scale structure around the RLLAB, B3 J2330+3927. This discovery is unlikely to be serendipitous. If we use the upper limit of the number density of 100 kpc-scale LABs from previous blind surveys for LABs at $z = 2 - 5$ [Saito et al. 2006; Smith & Jarvis 2007; Yang et al. 2009], the estimated probability to find a new 100 kpc LAB in the survey volume of our observation is only $< 5\%$. Thus it is more likely that this large-scale structure is a special environment for LABs to form. However, we need spectroscopic redshifts of the new RQLAB and the large-scale structure to investigate whether the new RQLAB and the RLLAB are really in the same structure or not.

On smaller scales, the new RQLAB appears to lie in the local density peak in the large-scale structure, while the RLLAB, B3 J2330+3927 does not. There are two possible interpretations of the difference of the local environments of these two LABs. Firstly, RQLAB may need a prominent ($\delta \approx 5$) density peak of galaxies to form through intense starbursts due to frequent galaxy interactions/mergers and/or continuous gas accretion in an overdense environment. The prototypes of RQLABs, SSA22 LAB1 and LAB2 are also known to reside in overdensities of star-forming galaxies of prototypes of RQLABs, SSA22 LAB1 and LAB2 are also continuous gas accretion in an overdense environment. The bursts due to frequent galaxy interactions/mergers and/or scale structure to investigate whether the new RQLAB and the large-scale structure are special environments for LABs to form. However, we need spectroscopic redshifts of the new RQLAB and the large-scale structure to investigate whether the new RQLAB and the RLLAB are really in the same structure or not.

We discovered a new candidate 100 kpc RQLAB, which appears to lie in the same large-scale structure around the RLLAB, B3 J2330+3927. This discovery is unlikely to be serendipitous. If we use the upper limit of the number density of 100 kpc-scale LABs from previous blind surveys for LABs at $z = 2 - 5$ [Saito et al. 2006; Smith & Jarvis 2007; Yang et al. 2009], the estimated probability to find a new 100 kpc LAB in the survey volume of our observation is only $< 5\%$. Thus it is more likely that this large-scale structure is a special environment for LABs to form. However, we need spectroscopic redshifts of the new RQLAB and the large-scale structure to investigate whether the new RQLAB and the RLLAB are really in the same structure or not.

On smaller scales, the new RQLAB appears to lie in the local density peak in the large-scale structure, while the RLLAB, B3 J2330+3927 does not. There are two possible interpretations of the difference of the local environments of these two LABs. Firstly, RQLAB may need a prominent ($\delta \approx 5$) density peak of galaxies to form through intense starbursts due to frequent galaxy interactions/mergers and/or continuous gas accretion in an overdense environment. The prototypes of RQLABs, SSA22 LAB1 and LAB2 are also known to reside in overdensities of star-forming galaxies of greater than $\delta \approx 5$ [Steidel et al. 2000]. On the other hand, RLLAB may not always need a prominent density peak to form if it is mainly powered by its radio and AGN activities. Alternatively, both RQLAB and RLLAB may need prominent density peaks to form but we could not completely trace the density of galaxies because we missed evolved and dusty galaxies in our survey. B3 J2330+3927 has two possible sub-mm companions although neither has a LAE/LAA counterpart [Stevens et al. 2003]. Thus it is still possible that B3 J2330+3927 is associated with an overdense region of evolved and dusty galaxies. Future deep, wide-field NIR and sub-mm observations will be useful to investigate these possibilities by providing a complete map including evolved and dusty galaxies in these environments.
