It has been suggested that transition metal ions such as iron can produce an oxidative injuries to nigrostriatal dopaminergic neurons, like Parkinson’s disease (PD) and subsequent compensative increase of tetrahydrobiopterin (BH₄) during the disease progression induces the aggravation of dopaminergic neurodegeneration in striatum. It had been established that the direct administration of BH₄ into neuron would induce the neuronal toxicity in vitro. To elucidate a role of BH₄ in pathogenesis in the PD in vivo, we assessed the changes of dopamine (DA) and BH₄ at striatum in unilateral intranigral iron infused PD rat model. The ipsistriatal DA and BH₄ levels were significantly increased at 0.5 to 1 d and were continually depleting during 2 to 7 d after intranigral iron infusion. The turnover rate of BH₄ was higher than that of DA in early phase. However, the expression level of GTP-cyclohydrolase I mRNA in striatum was steadily increased after iron administration. These results suggest that the accumulation of intranigral iron leads to generation of oxidative stress which damage to dopaminergic neurons and causes increased release of BH₄ in the dopaminergic neuron. The degenerating dopaminergic neurons decrease the synthesis and release of both BH4 and DA that are relevant to the progression of PD. Based on these data, we propose that the increase of BH₄ can deteriorate the disease progression in early phase of PD, and the inhibition of BH₄ increase could be a strategy for PD treatment.

Key Words: Dopamine, Ferrous citrate, GTP-cyclohydrolase I, Parkinson’s disease, Tetrahydrobiopterin

INTRODUCTION

Parkinson’s disease (PD) is a neurodegenerative disorder affecting 1% of population above the age of 65 [1] and is characterized by selective loss of dopaminergic neurons in the substantia nigra pars compacta (SNC). Degradation of the dopaminergic neurons located in the SNC and a subsequent loss of dopaminergic nerve terminals in the striatum are responsible for most of the movement disorders [2]. Although the underlying cause of dopaminergic cell death or process by which these cells degenerate in PD is not clearly understood but oxidative stress [3], mitochondrial dysfunction [4], apoptosis [5-7] and protein misfolding [8] are thought to play an important role in causing dopaminergic cell death and cellular degeneration.

Within the central nervous system, tetrahydrobiopterin (BH₄) is an essential cofactor for dopamine (DA) and serotonin synthesis. The BH₄ is an obligatory cofactor for tyrosine hydroxylase (TH), the first and rate limiting enzyme in the dopamine synthesis and is produced selectively in monoaminergic neurons in the brain including the nigral dopaminergic neurons [9-11]. It has been reported that excess DA is potential source of oxidative stress [12] and is major contributing factor for nigrostriatal degeneration [13-15]. It has been demonstrated that BH₄ and DA together lead to generation of oxidative stress and render DA cells particularly vulnerable [16] and furthermore administration of BH₄ to animals leads to selective degeneration of the DA system [17]. BH₄ itself generates oxidative stress by undergoing auto-oxidation [18-21] and elicits the formation of reactive quinoid derivatives of DA and protein as well as lipid peroxidation in DA cells [22]. The amount of BH₄ synthesizing enzyme, GTP cyclohydrolase I (GTP-CH I), is lowest, suggesting that the level of BH₁ in this area might be normally subtoxic [23,24]. However, it is possible that conditions that lead to aberrant increase in BH₄ and DA might elicit oxidative damage at SNC.

It has been reported that transition metal ions like, iron

ABBREVIATIONS: PD, Parkinson's disease; SNC, substantia nigra pars compacta; BH₄, tetrahydrobiopterin; DA, dopamine; TH, tyrosine hydroxylase; GTP-CH I, GTP cyclohydrolase I; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; LC-MS/MS, liquid chromatography with triple quadrupole tandem mass spectrometer.
has dopaminergic neurotoxic properties similar to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) because of its capacity to inducing brain injury through the generation of reactive oxygen species and the acceleration of DA auto-oxidation [25]. The iron related striatal DA depletion or turnover via DA auto-oxidation or oxidative stress on PD animal models have been already reported [26] however the iron related striatal BH4 depletion or turnover via oxidative stress has not been studied yet. Hence, the present study aims to investigate the effect of intranigral infusion of ferrous citrate on DA and BH4 turnover in rat nigrostriatal system in the progress of PD. We also analyzed GTP-CH I mRNA expression in rat nigrostriatal system in parallel.

**METHODS**

**Animal handing and care**

All the experimental protocols involving animals were reviewed and approved by the institutional animal care and use committee (IACUC) of Dankook University. Male Sprague Dawley rats (250~300 g) were purchased from Daehan Biolink, Korea and upon the arrival, the animals were housed three per cage for two weeks at room temperature of 22±2°C and relative humidity 60~70% on a 12-h light-dark cycle with adequate supply of standard rodent food and water *ad libitum*.

**Unilateral destruction of nigrostriatal dopaminergic neuron**

Ferrous citrate was diluted in sterile 0.9% NaCl solution to produce the concentration of 2 mM. The solution was filtered through 0.2 μm Minisart® filter unit and was used for intranigral administration. On the day of surgery, rats were anaesthetized with intraperitoneally (i.p.) injection of tiletamine hydrochloride (125 mg/kg) and zolazepam hydrochloride (125 mg/kg) and positioned on an ice plate to separate right (ipsilateral) and left (contralateral) striatum. Both striatum were safely stored at −80°C for subsequent analysis. The positive ion mode. The LC-MS/MS determination of DA and BH4

The modified method was used for simultaneous determination of DA and BH4 in brain sample by using liquid chromatography with triple quadrupole tandem mass spectrometer (LC-MS/MS) [28]. Briefly striatum was accurately weighed and mixed with acetonitrile containing 200 μg/ml dithiotreitol and 2 μg/ml cimetidine (internal standard). The homogenized mixture was vortexed for 30 sec and centrifuged (8,000 rpm, 10 min) for extraction of DA and BH4 from striatum. The clear supernatant was collected in 100 μL of microtube and was dried under gentle stream of nitrogen at 45°C. The dried extract was reconstituted with 100 μL of microtube and was injected into LC-MS/MS system. The sample was eluted with mobile phase and was analyzed under the multiple reaction monitoring (MRM) mode: DA (m/z 154 → 177, CE=10 eV), BH4 (m/z 242.2 → 166.0, CE=17 eV), cimetidine (m/z 253.1 → 159.0, CE=14 eV). The liquid chromatographic system was a Accella (Thermo Fisher Scientific Inc., Waltham, MA, USA) system equipped with a solvent delivery module, Nanospace SII-2 3133 (Shiseido Inc., Japan) with an autosampler, and connected to a Discovery Max (Thermo Fisher Scientific Inc.) quadrupole tandem mass spectrometer equipped with electrospray ionization. System control and data analyses were carried out with Xcalibur (Thermo Fisher Scientific Inc.). Chromatographic separation was achieved using a hydrophilic interaction chromatography HPLC column (Luna 3u HILIC 200A, Phenomenex, Torrance, CA, USA) protected by a guard column (Phenomenex C18, 4x2 mm, Phenomenex). A column oven (Nanospace SII-2 3004, Shiseido, Japan) was used online. The mobile phase of 0.1% formic acid-acetonitrile/water (75 : 25, v/v) was run at a flow rate of 300 μL/min. The electrospray ionization (ESI) mass spectrometer was operated in the positive ion mode.

**Total RNA isolation and reverse transcription**

The brain tissues were homogenized in TRizol® reagent (Invitrogen). Total RNA was extracted from the cells according to the manufacturer’s suggested protocol. Total RNA (2 μg) was treated with 1 U DNase I (Promega) for 15 min at RT in 18 μL of volume containing 1X PCR buffer and MgCl2 (2 mM). Then it was inactivated by incubation with 2 μL of EDTA (25 mM) at 65°C for 15 min. Reverse transcriptase reactions were carried out using MuLV Reverse Transcriptase (Promega) according to the manufacturer’s protocol. Each reaction tube contained 2 μg of total in a volume of 25 μL containing 5 μL of MuLV 5X RT buffer, 1 μg of oligo-d(T) (promega), 2.5 μL of dNTP Mixture (Promega), 40 U of RNAsin (Promega), 20 U of MuLV Reverse Transcriptase and nuclease-free water to volume. Reverse transcriptase reactions were carried out in a DNA Thermal Cycler 480 (Perkin Elmer, Branchburg, NJ, U.S.A.) at 25°C for 20 min, 42°C for 60 min and 95°C for 10 min. The cDNA was then stored at −20°C until use.

**Quantitative real time PCR**

Real-time PCR for the analysis of GTP-CH I mRNA levels were performed in a Rotor-Gene 3000 (Corbett life sciences, RG-3000, USA). QuantiTect SYBR Green PCR kit and primers (rat GTP-CH I and GAPDH genes) were purchased.
from Qiagen. The reaction mixture consisted of 2 μL of cDNA template, 10 μL of SYBR Green PCR master mix and 10 pmol of primers in total volume of 20 μL. The cDNA was denatured at 95°C for 5 min followed by 40 cycles of PCR at 95°C for 5 sec, 55°C for 10 sec and 72°C for 15 sec. Data acquisition and analysis of real-time PCR were performed using the Rotor-Gene 3000 series software. Delta-delta Ct method was used to calculate the relative quantitation of GTP-CH 1 normalized with GAPDH level in each individual sample.

**Statistical Analysis**

All values shown in the figures are expressed as the means±SEM obtained from at least three independent experiments. Statistical analysis was carried out one-way analysis of variance (ANOVA) with Tukey’s post-hoc test (Fig. 2~4) using GraphPad Prism (GraphPad Software, San Diego, CA, USA). Statistically significant differences between groups were assumed when p<0.05.

**RESULTS**

**Histological verification of unilateral intranigral iron infusion**

As the preliminary experiment, upon completion of the microinfusion of ferrous citrate into SN, the animals were anaesthetized with i.p. injection of tiletamine hydrochloride (125 mg/kg) and zolazepam hydrochloride (125 mg/kg) and transcardially perfused with 10% formalin (neutral buffered, pH 7.4). The brains were separated and immersed in the fixative for overnight and then brain tissues were cryoprotected after soaking in a series of sucrose solution (10%, 20%, and 30%) at 4°C until they sank in liquid nitrogen. Serial coronal section, 40 μm were cut with freezing, sliding microtome and stained with cresyl violet. The image shows that injected microdialysis probe tips were located in the SN which was stained with iron (Fig. 1).

**Observation of behavioral response after unilateral intranigral iron infusion**

After unilateral intranigral infusion of ferrous citrate, animals showed spontaneous contralateral circling behavior. Although spontaneous circling behavior gradually reduced after lesion, it was exaggerated by the application
Intranigral infusion of ferrous citrate caused changing DA levels in ipsilateral striatum (n=12) was 192.1±19.0 (ng/wet tissue weight g). The percentage ratio of BH4 concentration in the ipsilateral striatum (n=6) after stereotaxic iron infusion at different time intervals from 0 to 7 d were measured. The maximum ipsistriatal BH4 level was 244.7±22.0% at 1 d and ipsistriatal BH4 was severely depleted to 4.5±3.5% at 4 d after intranigral iron infusion (Fig. 3). The BH4 levels in ipsilateral striatum by the intranigral infusion of vehicle (n=4) with respect to percentage of contralateral striatum at 0 and 7 d were 94.9±12.3% and 96.3±11.7%, respectively. There were significant differences of ipsistriatal BH4 level between 0 d (before injection) and 0.5, 1, 2, 4, and 7 days after intranigral ferrous citrate administration (Fig. 3). These data showed that intranigral iron accumulation caused initial increase in BH4 levels in nigrostriatal dopaminergic neurons, which preceded chronic decrease in the striatal BH4 levels. The result showed that the turnover of BH4 and DA were significantly correlated (r=0.968, p<0.05) after iron infusion. However, striatal BH4 concentration increased further than DA concentration until 1 d but interestingly, decreased quickly after 1 d compared with striatal DA turnover in rat nigrostriatal system. It is suggested that the BH4 concentration changes more dynamically than the DA concentration in striatal system (Fig. 2 and 3).

**Fig. 4.** Changes of ipsistriatal GTP-CH I mRNA levels in intranigral iron infused rats. Total RNA was isolated from both ipsistriatum and contrastriatum of intranigral unilateral saline (4.0 μL) or ferrous citrate (4.0 μL, 2 mM) infused rats at 0, 0.5, 1, 2, 4, and 7 days after challenge. Gene expression of GTP-CH I was measured by quantitative real-time PCR using Rotor-Gene 3000. The mRNA level of GTP-CH I (ipsistriatum / contrastriatum) was normalized with GAPDH gene expression. Data were obtained from triplicated PCR reactions, and values are mean±SEM (*p <0.05, **p<0.01, ***p<0.001; compared to control group, n=6).

**Alteration of striatal DA level**

Intranigral infusion of ferrous citrate caused changing DA release in the striatum via nigrostriatal dopaminergic system. The average concentration of DA in the contralateral striatum (n=12) was 4328.5±26.3 (ng/wet tissue weight g). The percentage ratio of DA concentration between 0 d (before injection) and 0.5, 1, 2, 4, and 7 days after intranigral iron infusion at different time intervals from 0 to 7 d were measured. The maximum ipsistriatal DA level was 200.9±10.7% at 1 d and ipsistriatal DA was severely depleted to 2.7±1.1% at 4 d after intranigral infusion of 4 μL of 2 mM ferrous citrate (Fig. 2) The DA levels in ipsilateral striatum by the intranigral infusion of 4 μL of 0.9% NaCl (vehicle, n=4) with respect to percentage of contralateral striatum at 0 and 7 d were 97.0±3.7% and 98.9±6.7%, respectively. There were significant differences of ipsistriatal DA concentration between 0 d (before injection) and 0.5, 1, 2, 4, and 7 days after intranigral ferrous citrate administration (Fig. 2). These data showed that intranigral iron accumulation caused initial increase in DA levels in nigrostriatal system which induced oxidative stress, preceded chronic decrease in the striatal DA levels such as the progress of PD.

**Alteration of striatal BH4 level**

Intranigral infusion of ferrous citrate caused changing BH4 release in the striatum by nigrostriatal dopaminergic system in a similar pattern of DA release. The average concentration of BH4 in the contralateral striatum (n=12) was 3000. The mRNA level of GTP-CH I mRNA expression in the striatum. The percentage ratio of quantitative real-time PCR values for GTP-CH I mRNA expression on the ipsilateral striatum (n=6) to the contralateral side after stereotaxic iron infusion at different time intervals from 0 to 7 d were increased gradually up to 277.4±4.4% at 7 d after ferrous citrate administration (Fig. 4). The GTP-CH I mRNA expression by the intranigral infusion of vehicle with respect to percentage of ipsi-/contra-lateral striatum at 0 and 7 d were 101.2±5.2% and 106.2±9.3%, respectively. There were significant differences of GTP-CH I mRNA expression between 0 d and 0.5, 1, 2, 4, and 7 days after intranigral ferrous citrate infusion (Fig. 4). These data showed that intranigral iron accumulation induced GTP-CH I mRNA expression immediately and the induction of gene expression was sustained at least 7 d in striatum, suggesting increased GTP-CH I mRNA expression might be a compensatory process of BH4 which depleted by the degenerative progress of nigrostriatal dopaminergic neurons.

**DISCUSSION**

It has been known that trace metal, iron, was accumulated in brain with aging and induced oxidative stress in the basal ganglia, especially in the A9 dopaminergic neurons of SNC area [29]. Interestingly, non-heme iron was increased further in the SN of patients with PD [30-32]. In the present study, we had microinfused ferrous citrate, a small molecular weight iron complex, into the SNC area unilaterally as the pathophysiological animal model mimicking PD to study the pathogenic path of the PD. We found that iron caused a chronic depletion of striatal DA and BH4 levels, which was preceded by initial increase in striatal...
DA and BH₄ concentration. In line with our findings, BH₄ levels are decreased at 24 h in MPP⁺ (1-methyl-4-phenylpyridinium)-induced human dopaminergic model of PD [33]. Previous our findings show that MPTP induce the reduction of DA but not BH₄ level in striatum and SN [34]. Intrin- ral iron infusion induced nigral DA and BH₄ release into striatum peaked during 0.5 and 1 d after the stereotoxic procedure which suggested that initial increased synthesis and/or release of nigral DA and BH₄ induced by iron accu-
mulation augmented the oxidative damage to nigrostriatal dopaminergic neurons, and damaged nigrostriatal dop-
aminergic neurons represented reduced synthesizing ca-
pacity of DA and BH₄ as the biochemical phenotype in PD. Therefore, this intranigral iron infusion is a quite reliable model for PD because it showed both biochemical and beh-
vioral phenotypes of PD with slow progress even similar neu-
rochemical and behavior have been docu-
mented following infusion of dopaminergic neurotoxin MPTP and 6-hydroxydopamine in the nigrostriatal dop-
aminergic system [34-36].

It has been previously proposed that oxidative injury in PD may be caused by oxidants generated during enhanced DA turnover or iron-catalyzed DA auto-oxidation [37,38]. Iron induced hydroxyl radical generation and lipid perox-
idation may be caused, at least in part, by sustained DA turnover which was observed during first two days after iron infusion. Earlier reports indicated that iron induced striatal DA depletion is linked to the loss of tyrosine hy-
droxylase-positive neurons in the SN. The present study demonstrates that the degree of the nigrostriatal degener-
ation is correlated with, not only DA turnover, but also chronic depletion of striatal BH₄. Several studies showed that both hydroxyl radicals and iron have been implicated in the initiation and propagation of chain reaction of lipid peroxidation [30-32]. It has been well documented that iron caused sustained lipid peroxidation which induced cell membrane damage, calcium overload and eventually lead to cell death when the oxidative stress overwhelms the cel-
ular integrity [31]. Elevated non-heme iron is routinely found in the SNC in PD patients [32]. As suggested by Kim et al. [39], it is possible that an aberrant increase in BH₄ and DA might elicit oxidative damage in the SNC, and re-
sulting structural damage to nigrostriatal pathway.

BH₄ auto-oxidation could produce hydrogen peroxide and superoxide radical [18-21]. In addition, DA, with its syn-
thesis facilitated by BH₄, in turn undergoes auto-oxidation to form a reactive quinine species [18,22,24]. Indeed, DA derived quione production is elevated in which BH₄ pro-
vides its auto-oxidation products [18]. As both BH₄ and DA are inevitably produced within the same cells for DA neuro-
transmission, the DA cells would tend to be more vulner-
able especially under intranigral iron infusion conditions that result in overproduction of BH₄ and DA.

All the monoaminergic neurons and terminals in the CNS produce BH₄ and DA cells are vulnerable to high level of BH₄, most probably due to the higher rate of oxidation of DA compared with other catecholamine or serotonin [18,19]. Under, the normal conditions, the level of GTP-CH I ex-
pression in the nigrostriatal system is lower than in the other monoaminergic cells [23,24]. In addition, DA is nor-
mally sequestered in the storage vesicles by the action of vesicular monoamine transporter (VMAT) after synthesis in the cytosol, limiting its encounter with BH₄ [23]. There-
fore, an aberrant condition such as intranigral iron in-
fusion, would lead to initial overproduction of BH₄ and DA as the consequence of oxidative damage and then gradually depress the production of BH₄ and DA, in which GTP-CH I levels were increased after 24 h with compared to sham control (vehicle infused group).

This is the first study for demonstrating an overpro-
duction of BH₄ and DA actually occur in vivo in PD animal model. Iron accumulation in SN elevated BH₄ and its syn-
thesizing enzymes, GTP-CH I and DA. This result provides a strong support for current view in progression of PD that excessive DA is a contributing factor for nigrostriatal de-
geneneration. In addition, we demonstrate that intranigral in-
fusion of iron could generate a PD animal model for study-
ing pathophysiology and for developing preventive method of PD progress in vivo. In the present study we showed iron accumulation in SN causes increases in production of both BH₄ and DA and this concomitant elevation induces degen-
eration of the nigrostriatal pathway. As BH₄ can increase oxidative damage by auto-oxidation as well as by enhancing synthesis of DA, whose oxidation is in turn facilitated in the presence of BH₄, it is possible that the iron accumu-
lation in the dopaminergic neuron can increase BH₄ levels, which might be a primary etiologic factor of PD in aged brain.

ACKNOWLEDGEMENTS

The present research was conducted by the research fund of Dankook university in 2012.
