Dnipro Medical Academy of the Ministry of Health of Ukraine, Dnipro, Ukraine

The topicality of the problem of periodontal diseases is due to their significant prevalence. The purpose of this work is to study the dynamics of markers of bone metabolism in the process of treatment of generalized periodontitis of the II–III levels of severity with age-related osteoporosis and without osteoporotic changes in the skeleton. The examination and treatment of 104 patients, aged 63–78, equal ratio of men and women, was conducted. Among the selected patients, 49 persons had normal bone mineral density, while the remaining 55 had osteoporotic changes in the bone tissue of involutory genesis. All subjects were assessed for the following indicators: mineral density of jaw bone tissue (BMD) according to the results of the computer tomography, the concentration of C-Propeptide of Type I Procollagen (CICP) in blood plasma, the activity of tartrate-resistant acid phosphatase (TRAP), bone alkaline phosphatase (BAP), osteocalcin, parathyroid hormone in blood serum, concentration of β-CrossLaps in urine, total calcium and inorganic phosphorus content in blood with calculation of the Ca/P index. It was established that in patients with periodontitis of the II–III degree there was a decrease in the BMD of the alveolar bone in comparison with the control values (P < 0.05), whereas the presence of systemic osteopenia worsened the indices (P < 0.001). The least osteoregenerative activity, which was characterized by the decrease in BAP, TRAP and CICP levels, was registered in patients with generalized periodontitis of the III degree on the background of age-related osteoporosis (P < 0.05). In the patients with generalized periodontitis of the III degree of severity, at the beginning of treatment, a weak negative correlation was found between BMD and TRAP activity (r = –0.292, P < 0.05) and mean strength correlation – with β-CrossLaps in urine (r = –0.348, P < 0.01). The concentration of CICP positively correlated with the mineral density of bone tissue from the third month after the start of treatment (r = 0.312, P < 0.05). As a conclusion, the mineral density of alveolar bone in the process of treatment varies unevenly depending on the severity of generalized periodontitis and the character of osteoporotic changes in the skeleton. The biochemical markers of bone metabolism allow the balance of processes of bone resorption and formation to be determined in order to correct treatment of generalized periodontitis.

Keywords: periodontal diseases; osteopenia; bone mineral density; biomarkers.

Introduction

The problem of inflammatory-dystrophic diseases of periodontal tissues is highly relevant on account of the wide distribution of this disease among the population of Ukraine, complicated by delayed diagnostics; the rapidly progressing development of the pathological process; and also by the necessity of integrated and prolonged treatment. Moreover, generalized periodontal disease is a serious socio-economic problem caused by a significant loss of teeth and decrease in the quality of life (Lu et al., 2016; Frencken et al., 2017). Currently, the diseases are classified as multi-factor diseases which are the result of interaction of the organism with the environment (Tsepov et al., 2016). Milder forms of generalized periodontal disease usually are nosologies, whereas severe forms are related to different systemic diseases which are characterized by general disorders of homeostasis (Fastovets, 2000; Linden et al., 2013). Practically always, hormonal disorders such as diabetes mellitus (Wu et al., 2015; Winning &Linden, 2017), endemic goiter (Chornij & Shmanko, 2017), menopause (Kolte et al., 2017; Goyal et al., 2017), states of immune deficiency, especially HIV infection (Souza et al., 2017), leukemia (Rinčić et al., 2016), and disorders of the development of connective tissue, for example its dysplasia (Kirova et al., 2009), are associated with generalized periodontal disease.

Currently, the pathogenic relation between the inflammatory process in the periodontal tissues and destructive changes in the alveolar bone is proved (Wang & McCauley, 2016; Kinane et al., 2017). However, recent research is not unanimous regarding the peculiarities of the development of periodontal disease during osteoporotic changes in the skeleton (Darcey et al., 2013; Chambrone, 2016), and also regarding the leading mechanism of destruction of the osseous component of periodontal disease (Bernal et al., 2018). It has been mentioned that with aggressive forms of periodontal disease, the number of osseous tooth deposits is minimum, whereas the resorption of bone tissue is significant (Clark et al., 2017).

The bone tissue is a connective tissue with a high level of mineralization of organic intercellular substance which contains around 70% of non-organic compounds, mostly calcium phosphate. Despite the high level of mineralization, constant renewal of the matrix and adaptive restructuration occurs in the bone tissues depending on the conditions of their functioning (Sims & Gooi, 2008). The bone tissue’s resistance to resorption depends on the level of its mineralization, which is determined by the main factors (Penoni et al., 2016). The main factors which...
influence the metabolism of bone tissue are the levels of calcium, phosphorus and hormones, which regulate their metabolism, circulating in the extracellular fluid (Naot & Cornish, 2008). The most informative markers of bone metabolism, often used in clinical studies, are considered to be the tartrate-resistant acid phosphatase (TRAP) of blood serum and C-terminal Telopeptide of Type-I Collagen (β-CrossLaps) of urine, which reflect the activity of resorptive processes. At the same time, osteocalcin (OC), bone alkaline phosphatase (BAP), procollagen type 1 C-terminal propeptide (CICP) of blood serum are most representative of the activity of processes of bone formation (Lu et al., 2016; Garniero, 2017). On the whole, the determination of the dynamics of concentration of the markers of resorption and formation of bone tissue in biological fluids is required in order to assess the success of treatment in effecting remission of the destructive processes in the bone tissue.

Apart from the abovementioned biochemical studies, numerous noninvasive apparatus methods of diagnostics have been developed and broadly introduced into clinical practice. They allow accurate determination of the mineral density of the bone tissue (Dobrovolskaja et al., 2017). Thus, the usage of roentgenological investigation allows not only study of the structure of bone tissue of the periodontal complex, but also determination of whether the patient is in the risk group of development of periodontal disease (Gajdarova et al., 2006; Igsniak et al., 2016), whereas the data from orthopantomography are a reason for roentgenological densitometry (Nakamoto et al., 2008).

Finally, considering that systemic osteoporosis is a significant mechanism which leads to the development and complication of generalized periodontal disease (Boddu et al., 2016), it is necessary to prescribe specific pathogenic therapy depending on the character of the metabolic disorders in the bone tissue (Gorb-Gavril'chenko & Streč'chenja, 2013; Aspalli et al., 2014; Mordasov & Ivanjuta, 2016). As a result of the close relationship between the mineral metabolism and the pattern of systemic osteoporosis, many clinicians recommend combined pharmacotherapy using anti-resorptive preparations, calcium and vitamins (Karakov, 2016). Selecting the optimum medicamental protocol, monitoring of the efficiency of treatment in dynamics, which includes timely correction, is impossible without determining and monitoring the structural-functional condition of the bone tissue (Masheiko, 2017; Roschger et al. 2008).

Therefore, considering everything stated above, the objective of this study was to determine the dynamics of biochemical markers of metabolism of bone tissue in the process of treatment of generalized periodontal disease of II–III degree among patients with age-related osteoporosis and no osteoporotic changes in the skeleton.

Materials and methods

For realisation of the goal, we conducted an integrated study and treatment of 104 patients with generalized periodontal disease of II–III degree, aged between 63–78 years, with an equal number of men and women. To diagnose periodontal disease, we used the classification of M. F. Danilevskij (Danilevskij & Bortisenko, 2000). Among the selected patients, 49 had normal mineral density in the bone tissue, whereas 55 had osteoporotic changes in bone tissue of involve genesis. The condition of bone tissue was determined on the bases of the results of studying the mineral density of the bone tissue (BMD) using the method of dual-energy X-ray absorptiometry using the Lunar Prodigy apparatus. Measurements were made in the lumbar vertebrae (L-LIV), in the area of femoral neck (Neck), greater trochanter (Troch), and Ward's triangle (Ward). Diagnosing osteoporotic changes in the skeleton was conducted in accordance with the recommendations of the WHO, criteria T, i.e. in relation to the value of standard deviation (SD) from the normal parameters of peak bone mass of healthy individuals of a corresponding age. The SD value below 1 was considered normal, between 1 and 2.5 SD – osteopenia, below 2.5 SD – osteoporosis (Siris et al., 2014).

Criteria for excluding patients from the scope of the study were as follows: the general diseases in the anamnesis, which could influence the mineral density of bone tissue; usage of medical preparations which contain mineral components; traumas and inflammatory diseases of the bone-joint system, breach of the treatment protocol.

Prior to the study, the patients gave written approval for being involved in the study.

The patients were divided as follows: 55 patients with semile osteoporosis were included in the first main group, group I (12 men and 15 women, who had generalized periodontal disease of II degree of severity) and the second main group, group II, which included 10 men and 18 women with aggressive (III type) disease. The comparison group was formed similarly to the main group in relation to gender and clinical criteria from people who had normal parameters of mineral bone density. Therefore, the comparison group I included 14 men and 9 women with periodontal disease of the II type; the comparison group II – 16 men and 10 women with periodontal disease of the III type. Also, as the control, we involved 20 people of the same age group with an equal number of men and women, with conditionally healthy periodontal tissues, who had no diagnosed osteoporotic changes in the bone tissue.

All patients suffering from generalized periodontal disease received complex treatment according to the generally accepted protocol (Borysenko et al., 2005). Prior to the treatment the patients underwent a professional hygiene regime of the oral cavity, which consisted of removing the sediments above and under the gums using the “Piezon-Master” ultrasonic system and the “Vektor” system. For providing long term stabilization of the pathological process, the dental treatment included therapeutic, surgical and orthopedic methods, and also consultations and treatment recommended by an endocrinologist.

In the scope of the presented study, all the observed patients were monitored using computer tomograpanic scanning of the jaw bones (Morita, Japan, 2008) to determine destructive changes in the compacted and trabecular bone, and at the same time determine the parameters of BMD in the following zones: alveolar, middle and apical horizontal, septal vertical. Alveolar horizontal was considered a conventional line which lay along the crest of alveolar process; middle horizontal – line which lay across the central part of interdental septum; apical horizontal – line which connects the tops of the roots, septal vertical – line which divides the alveolar line into equal parts in lengthwise direction. The density of the bone tissue was expressed in Hounsfield numbers (H).

The conclusions on the activity of the processes of destructive bone tissue were made according to the level of the resorption markers. In the blood serum, we determined the activity of tartrate-resistant acid phosphatase (TRAP) (u/l) using a set of Bone-TRAP (IDS). The concentration of β-CrossLaps fragments in the urine were determined using the Serum CrossLaps (Osteometer) test-system.

For standard excretion of β-CrossLaps, we used the second spontaneous morning sample of urine with following normalization of its concentration to the amount of creatinine in the analyzed sample. The results were converted into ng β-CrossLaps to 1 g of creatinine.

The activity of recovery of the bone tissue was determined according to the concentration of procollagen type 1 C-terminal propeptide (CICP) in the blood serum, which was determined using the method of immune-enzymic analysis with Metra CIPC ELA Kit («Quidel Corporation», USA) diagnostic set, bone alkaline phosphatase (BAP) in the blood serum using kinetic colorimetric method (U/l), osteocalcin with N-MID Osteocalcin ELISA (USA) test set.

In addition, we calculated the parameters of mineral metabolism – concentration of parathyroid hormone in the blood serum using the “1-PTH ELISA” (DSL, USA) test-system; the content of total calcium in the blood by the colorimetric method with Ortho-Cresolphthalein (Kapitanenko & Dochkin, 1988); the content of total non-organic phosphorus in the blood by the colorimetric method according to the reaction with Molybdenum-Vanadium reagent (mmol/l) (Kondrahin, 2004) with following calculation of the Ca/P proportion.

The obtained data were statistically analyzed in Statistica 6.0 (Statsoft Inc., USA) pack using the calculation of the Student’s t-criterion at normal distribution of the data and non-parametric Mann-Whitney test criterion at not normal distribution. The normal distribution was calculated using the Shapiro-Wilk test criterion. Differences
Results

As we see from the data provided in Table 1, in each group, the most significant changes in the bone tissue density which occurred as a result of the course of treatment were observed in the septal vertical, and also in the alveolar and middle horizontals, i.e. in the areas directly involved in the pathological process of generalized periodontal disease. At the same time, in the alveolar horizontal, the BMD parameters were higher (P < 0.05), though the dynamics of the changes in the process of treatment were similar to other areas of the jaw bones (P > 0.05). The lowest changes in BMD were observed in the apical horizontal, which is explained by the remoteness of this area from the inflammation source localized in the interalveolar septa (P < 0.001).

Separate mention should be made of the significant dependency of the peculiarities of localization of the destructive process on the BMD parameters among the patients with generalized periodontitis. In patients suffering from generalized periodontitis of the III type with predominant vertical type of destruction of the bone tissue, the BMD parameters in certain areas were reduced to 600 H. The determined reduction of the mineral density was followed by disorders in the bone structure manifested by loss of clarity of the trabecular pattern, thinning of the trabeculae. The described pattern of the pathological process is related to its localization mostly in the areas of cancellous bone tissue, where the metabolic processes take place very actively. Thus, in the abovementioned observations, the bone tissue was affected by active resorption, which was manifested in rapid decrease in the BMD parameters.

The greatest decrease in the BMD parameters was observed in the alveolar horizontal among the patients suffering from generalized periodontitis which developed following systemic osteoporotic changes in the bone tissue (main groups I and II). The determined parameters of these groups were higher compared to the comparison groups I and II by 12.3 ± 3.2% (P > 0.05) and 14.1 ± 3.5% (P > 0.05) on average respectively and by 24.0 ± 4.1% (P < 0.01) and 32.1 ± 4.6% (P < 0.001) respectively compared to the control group.

However, later, in the process of treatment, we observed gradual normalization of the parameters of mineral bone density among the patients of both experimental groups (P < 0.001). One month after the beginning of the treatment, the BMD parameters of the II group of comparison had practically normalized and were close to the parameters of the control, maintaining at this level throughout the monitoring (P > 0.05). In the II group of comparison, the BMD parameters recovered gradually, which was manifested in clinical-X-ray stabilization of the pathological process in the periodontal tissues, though they did not equalize with the parameters of the control (P > 0.05).

At the same time, mineral density of the bone tissue of the patients with generalized periodontitis of the II type (main group I), despite the treatment, remained practically unchanged, and 3 months after the beginning of the treatment it had increased only by 6.1 ± 1.8% from the initial parameters (P > 0.05). A similar insignificant increase was recorded in the next monitoring period. By contrast, during the treatment, the patients of main group II were observed to have a negative dynamic of the BMD parameters. Therefore, 1 month after the beginning of the treatment, the mineral density of the bone tissue had decreased by 4.2 ± 1.2% on average from the initial parameters, and after 3 months – by 6.5 ± 1.8%, having stabilized and demonstrating an insignificant positive dynamic 6 months after the beginning of the treatment (P > 0.05).

The results of the conducted biochemical studies, presented in Table 2, indicated that the level of total calcium in the blood before the treatment of generalized periodontitis in the comparison groups was already in the 3rd month since the treatment began (P < 0.05). By contrast, in all patients of the main groups the level of blood phosphates remained significantly lower than the parameters of the control throughout the study. Also, the prevailing of bone tissue resorption over the processes of its regeneration was indicated by the Ca/P proportion which was much lower than 1.0. In the patients with generalized periodontitis in the main groups I and II this indicator equaled 0.82 ± 0.08 and 0.63 ± 0.07 respectively (P < 0.05 compared to the control).

As we see in Table 2, the systemic osteoporotic phenomenon among the patients with generalized periodontitis was manifested in increase in the concentration of β-CrossLaps fragments in the urine (P < 0.05). And despite the fact that during the study, the patients of the main groups I and II were observed to exhibit a tendency towards decrease in its secretion, this parameter remained heightened even during the period remote from the beginning of the treatment, which indicates

|           | after 6 months      | 887.3 ± 133.8*    | 1020.5 ± 158.1   | 1143.5 ± 128.7  | 893.8 ± 133.4  |

Note: * – the difference is statistically reliable at P < 0.05; ** – P < 0.01, *** – P < 0.001 compared to the parameters of the control.

In the experimental groups, at the beginning of the treatment, the level of phosphorus in the blood of patients with generalized periodontitis of the III type was higher than the control parameters (P < 0.05), indicating the prevalence of the bone resorption over the processes of bone tissue formation, unrelated to the mineral density of the skeleton.

However, in comparison group II, we recorded a decrease in the concentration of phosphorus in the blood serum to its normalization already in the 3rd month since the treatment began (P < 0.05). By contrast, in all patients of the main groups the level of blood phosphates remained significantly lower than the parameters of the control throughout the study. Also, the prevailing of bone tissue resorption over the processes of its regeneration was indicated by the Ca/P proportion which was much lower than 1.0. In the patients with generalised periodontitis in the main groups I and II this indicator equaled 0.82 ± 0.08 and 0.63 ± 0.07 respectively (P < 0.05 compared to the control).
resorption which gradually involved previously unaffected areas of the alveolar bone, and also possible progression of osteoporotic changes in other areas of bone.

A positive change in the process of bone recovery among the patients with generalized periodontitis was the normalization of the level of acid bone phosphatase a month after the treatment started in the I main group and 3 months after the beginning – in main group II (P < 0.001). Similar dynamic indicates gradual transformation of progressive resorption of bone tissue in its latent process following decrease in the total proinflammatory potential as a result of the treatment.

### Table 2
Changes in the biochemical parameters of metabolism of bone tissue in the blood and urine of the patients of the main groups (n = 49) and comparison groups (n = 55) over the treatment process compared to the control (M ± m, n = 20)

| Group | TRAP, U/l | β-CrossLaps, ng/g creatinine | Osteocalcin, ng/ml | BAP, U/l | CICP, ng/ml | Parathormone, pg/ml | Total blood calcium, mmol/l | Total non-organic phosphorus of blood, mmol/l |
|-------|-----------|-------------------------------|--------------------|----------|-------------|---------------------|-----------------------------|---------------------------------------------|
| Control | 4.88 ± 0.14 | 1.02 ± 0.05 | 16.64 ± 0.43 | 10.73 ± 0.34 | 61.82 ± 2.45 | 47.84 ± 3.27 | 2.32 ± 0.11 | 1.91 ± 0.16 |
| Before treatment | 5.20 ± 0.16 | 1.12 ± 0.09 | 16.45 ± 0.44 | 11.82 ± 0.43 | 60.73 ± 2.56 | 46.78 ± 3.41 | 2.21 ± 0.12 | 2.05 ± 0.21 |
| After 1 month | 5.11 ± 0.17 | 1.09 ± 0.07 | 18.22 ± 0.48* | 11.59 ± 0.33 | 68.02 ± 2.48 | 47.12 ± 3.37 | 2.18 ± 0.14 | 1.98 ± 0.18 |
| After 3 months | 5.12 ± 0.08 | 1.04 ± 0.08 | 17.93 ± 0.57 | 11.52 ± 0.38 | 71.09 ± 2.63* | 46.84 ± 2.82 | 2.38 ± 0.11 | 2.07 ± 0.15 |
| After 6 months | 5.05 ± 0.13 | 1.06 ± 0.09 | 18.64 ± 0.65* | 11.45 ± 0.34 | 64.30 ± 2.57 | 47.51 ± 3.25 | 2.29 ± 0.13 | 1.86 ± 0.12 |

Notes: * – difference is statistically significant at P < 0.05, ** – P < 0.01, *** – P < 0.001 compared to the parameters of the control.

The highest level of alkaline phosphatase, which indicates the active processes of collagen synthesis in the bone tissue, was observed among the patients of comparison group I, whereas, the patients of the main groups and II had values of this parameter (P = 0.05). In the patients with generalized periodontitis of the III type, which followed osteoporotic changes in the skeleton, the activity of the bone alkaline phosphatase decreased from the control values by 21.8 ± 4.2% (P < 0.001). The latter, perhaps, was caused by the inhibition of the functional activity of the osteoblasts which accompanied the damage to a large volume of the bone tissue, which occurred among the patients.

At the same time, the level of parathormone in all the experimental groups remained within the norm, though in the main groups, we observed a tendency towards the increase of its level to the upper border of the norm, caused by low level of calcium in the blood. Excessive secretion of parathormone following the hypocalcemia additionally activates osteoporogeneter, which justifies the prescription of the calcium preparations and vitamin complexes during treatment of destructive forms of generalized periodontal disease (Leonova et al., 2013; Hellslein, 2011).

It is interesting that the dynamic changes in the level procollagen type 1 C-terminal propeptide (CICP) in the blood plasma, which describes the activity of osteoblasts, was different from the pattern of changes of other parameters of osteoregeneration. The highest CICP level observed in comparison groups I and II indicates that despite that decrease in the mineral density of bone tissue of bones of the jaw and significant prevalence of bone resorption over osteosynthesis among the abovementioned patients, the process of bone tissue recovery is developing at a sufficient level. Also, we should mention that the CICP level in the blood plasma normalized 1–3 months after the beginning of the treatment among the patients of the comparison groups. However, in the patients of the main groups the initial CICP level, which was lower by 22.6 ± 4.0% compared to the control (by 26.0 ± 4.3% for the main group II), normalized only 3–6 months after the treatment (P < 0.05).

The same dynamic was observed for the parameters of bone alkaline phosphatase and osteocalcin (Table 2). However, due to significant variation of its parameters, the determined differences compared to the control were statistically unreliable (P > 0.05). On the whole, the determined difference of the parameters of the bone formation reflects the decrease in the activity of the osteogenration processes among the patients with generalized periodontitis, who had osteoporotic changes in the entire skeleton.

After generalization and analysis of the quantitative parameters determined for the experimental groups during different periods of the treatment, we conducted a correlation-regression analysis to determining the most significant relations between the indicators of mineral density of the bone tissue (BMD) and biochemical markers of bone metabolism. For the abovementioned analysis, we selected the parameters which changed the most during the treatment: mineral density of the bone tissue in the alveolar and middle horizontal, concentration of tartrate-resistant acid phosphatase (TRAP), bone alkaline phosphatase, procollagen type 1 C-terminal propeptide (CICP) in the blood and β-CrossLaps fragments in urine. The calculated correlational relations are presented in the Table 3 and 4.

### Table 3
Correlational relationships (r) between the parameters of bone tissue mineral density of the lower jaw in alveolar horizontal and biochemical parameters of bone tissue metabolism among the patients of the experimental groups during the treatment (n = 104)

| Group | TRAP | β-CrossLaps | BAP | CICP |
|-------|------|-------------|-----|------|
| Before treatment | 0.368* | 0.386** | -0.188 | 0.214 |
| After 1 month | -0.327 | 0.325 | 0.155 | 0.247 |
| After 3 months | -0.264* | -0.341* | 0.236* | 0.281* |
| After 6 months | -0.180 | -0.307 | -0.146 | 0.319** |

Notes: * – the difference is statistically reliable at P < 0.05, ** – P < 0.01.
After the relationships between the mineral density of the jaws in the alveolar horizontal (BMD) and parameters of bone tissue metabolism were calculated, in the main groups and comparison groups, we found a relatively low and average negative relation between this parameter and TRAP concentration in the blood and β-Cross.Laps in the urine during the first three months of monitoring (P < 0.05). It is interesting that the further correlation of the abovementioned parameters had a low level of probability (P > 0.05), which indicates the impact of proinflammatory markers on the destruction of bone tissue, and, therefore, the values of the BMD parameters at the beginning of the treatment. However, during the treatment, the levels of the abovementioned markers gradually decreased and their impact on the parameters of bone mineral density was reduced (see Table 3).

For both experimental groups, we calculated a low positive correlational relationship between bone mineral density and CICP concentration in the blood plasma, which had a sufficient level of significance, beginning from the third month of monitoring (P < 0.05). In our opinion, it was present due to the BMD dependency on the balance between the proinflammatory and osteoregenerating factors, and its changes were caused by the increase in the activity of the processes of bone tissue mineralization which occurred in the final stage of osteoregeneration a few months after the beginning of treatment. At the same time, in comparison group I, the correlational relation was less significant due to lower loss of the bone mass, i.e. a lower impact of these markers on the bone mineral density parameter.

During the comparison of bone mineral density of the alveolar process in the middle horizontal and the indicators of bone tissue metabolism (see Table 4) among the patients of the main group, we determined a statistically significant average negative relation in the main groups with β-Cross.Laps concentration throughout the monitoring and a low relation with TRAP at the beginning of the treatment (P < 0.05). In comparison group II, a similar pattern was determined until the third month of monitoring.

Perhaps, the presence of the abovementioned relations is due to the fact that bone tissue of the alveolar process in the middle horizontal is not directly involved in the inflammatory process in patients with generalized periodontitis, i.e., its resorption level is less than TRAP-conditioned, therefore following osteoporosis, the bone mineral density depends also on other components of the bone homeostasis. This is proved by the extent of correlation of this parameter, which remained quite high with the β-Cross.Laps concentration (P < 0.05).

Table 4

| Group          | TRAP | β-Cross.Laps | BAP | CICP |

Note: * – difference was statistically reliable at P < 0.05.

Finally, a low positive correlational relationship between BMD and CICP concentration was determined in the comparison groups from the first month of monitoring, whereas in the main groups this began in the third month (P < 0.05). This allows us to conclude that the CICP is good at reflecting the processes of osteoregeneration and remineralization of bone tissue which was not directly involved in the inflammatory-dystrophic process.

Finally, we should summarize the data obtained over the treatment of the patients with generalized periodontitis in the different experimental groups. The highest percentage of stable remissions 6 months after the treatment began was recorded in the I main group and the I comparison group, i.e. among the patients with generalized periodontitis of the II type, who had osteoporotic changes in the skeleton, or did not have them. The treatment efficiency parameters equaled 74.1 ± 8.4% (20 of 27) respectively for the I main group and 78.3 ± 8.6% (18 of 23) for the I comparison group (P > 0.05). Far worse results were observed in the II comparison group (patients with generalized periodontitis of the III type with no systemic involutory osteoporotic changes of bones), where the clinical-X-ray stabilization of the disease was observed only in 33.8 ± 9.8% (14 of 26) of the observations (P < 0.05). In the II main group, i.e. the patients with the periodontitis of the III type, which had developed following systemic osteoporotic disorders in the bone tissue, the stable remission 6 months from the beginning of the treatment was recorded only in 8 of 28 patients (28.6 ± 8.5%, P < 0.05). Therefore, the efficiency of the treatment significantly decreases in patients with advanced development of the inflammatory-dystrophic process in the tissues around the teeth. At the same time, the presence of systemic disorders in the bone metabolism complicates the clinical symptomatic, causes more significant imbalance of the resorption-regeneration processes in the alveolar bone, and, therefore complicates the treatment.

Discussion

Generalized periodontitis should be analyzed as an inflammatory-dystrophic multi-factor process in the tissues around the teeth, the development of which depends both on genetic predisposition and external factors, and also individual peculiarities of the metabolic profile of the patient, and finally, the systemic diseases suffered by this patient (Wu et al., 2015; Tsepov et al., 2016; Souza et al., 2017).

Osteoporosis of involutory genesis is a non-favourable factor which complicates generalized periodontal disease, which, first of all, manifests in decrease of the bone mineral density (BMD), particularly the alveolar process (Boddur et al., 2016). Considering the fact that the alveolar bone is within the source area of the inflammatory-destructive process initiated by the microbial invasion of the periodontal tissues, rapid progression of the bone resorption develops. Also, bone tissue with decreased mineral density has lower reserve potential for recovery, even after eradication of the main periodontopathogenic factors.

Therefore, it is pretty clear that without determining the causes of systemic disorders in the bone tissue, and also their elimination, it is practically impossible to achieve prolonged remission of generalized periodontal disease and eliminate the risk of development of relapse and progression of the pathological process (Mordasov & Ivanjuta, 2016). Thus, it is recommended to supplement the main complex treatment of generalized periodontosis by calcium preparations, mineral complexes, and preparations which normalize metabolic processes, particularly in bone tissue (Hellsstein et al., 2011; Leonova et al., 2013). Moreover, in cases of diagnosed osteoporosis of patients with generalized periodontal disease, it is recommended to prescribe antosteoporotic preparations (Gorb-Gavriltchenko & Strelchenja, 2013; Aspilli et al., 2014). In our opinion, such an approach is entirely justified. However, treatment of osteoporosis cannot be within the competency of only a periodontist and requires participation of specialists in the field.

Certainly, prescribing antiresorptive preparations, as with monitoring the dynamic of changes in bone tissue as a result of treatment is impossible without determining the parameters of bone mineral density (BMD) and study of biochemical markers of bone metabolism. As the results of our study indicate, bone mineral density changes in a nonuniform manner depending on the severity of generalized periodontosis and manifestation of osteoporotic changes in bone density. In our opinion, this is caused by the fact that the pattern of processes of destruction and recovery of the bone matrix is determined by...
pumflammatory, osteomodeling and osteoregeneration factors, the proportion of which changes and determines the condition of bone tissue at different stages of treatment.

The results we obtained indicate a close relationship between the treatment results and initial periodontal status of patients, i.e. much worse prognosis of treatment outcome in groups with higher level of disease severity, which is proved by the works by our colleagues (Boddu et al., 2016; Bernal et al., 2018). On the other hand, we demonstrated that the systemic disorders in bone metabolism, particularly involutory genesis, radically complicate the inflammatory-dystrophic process in the tissues around the teeth, decreasing the efficiency of treatment. Therefore, there is a need to adjust the treatment protocol for the abovementioned patients.

Conclusions

The most diagnostically valuable indicators of the condition of bone tissue of patients with generalized periodontal disease of II–III type of severity following involutory osteoporosis with no systematic changes in mineral bone density are the parameters of bone mineral density of the alveolar bone (BMD), and also the β-CrossLaps level in urine and activity of tartrate-resistant acid phosphatase (TRAP) and bone alkaline phosphatase in the blood serum.

The most representative indicator of the inflammatory-destructive process in periodontal disease is decrease in bone mineral density in the alveolar part of jaw bones. This parameter decreases in patients with II type of severity by 13.4 ± 3.2% compared to the control, and in patients with III type by 20.1 ± 3.5% (P < 0.05). Systemic osteopenic phenomena cause even greater decrease in this parameter to values which in patients with generalized periodontosis of II type of severity were 24.0 ± 4.1% lower than the control level, and lower by 32.1 ± 4.6% (P < 0.001) in patients with III type.

The lowest osteoregenerative activity occurred at the beginning of treatment of patients with generalized periodontal disease of III type, which followed systemic involutory osteoporosis. Therefore, the activity of bone alkaline phosphatase decreased by 21.8 ± 4.0% compared to the control; tartrate-resistant acid phosphatase (TRAP) and bone alkaline phosphatase in the blood serum.

The main proinflammatory markers on the BMD parameters gradually decrease in the process of treatment, whereas the positive dynamic of osteoregenerative parameters indicate processes of bone tissue recovery, which is recorded only from the third month of monitoring. The mineral metabolism parameters have only supportive significance for assessing bone metabolism.

The patients suffering from generalized periodontal disease of III type of severity have a low negative relationship between mineral density of the alveolar part of the jaw bones and activity of TRAP in the blood (r = –0.292, P = 0.05) and relationship of average extent of concentration of β-CrossLaps in the urine (r = –0.348, P < 0.01). At the same time, concentration of procollagen type I C-terminal propeptide (CICP) – by 26.0 ± 4.3% (P < 0.05).

The main proinflammatory markers on the BMD parameters gradually decrease in the process of treatment, whereas the positive dynamic of osteoregenerative parameters indicate processes of bone tissue recovery, which is recorded only from the third month of monitoring. The parameter least osteoregenerative activity occurred at the beginning of treatment of patients with generalized periodontal disease of II type, which followed systemic involutory osteoporosis. Therefore, the activity of bone alkaline phosphatase decreased by 21.8 ± 4.0% compared to the control; tartrate-resistant acid phosphatase (TRAP) and bone alkaline phosphatase in the blood serum.

The most representative indicator of the inflammatory-destructive process in periodontal disease is decrease in bone mineral density in the alveolar part of jaw bones. This parameter decreases in patients with II type of severity by 13.4 ± 3.2% compared to the control, and in patients with III type by 20.1 ± 3.5% (P < 0.05). Systemic osteopenic phenomena cause even greater decrease in this parameter to values which in patients with generalized periodontosis of III type of severity were 24.0 ± 4.1% lower than the control level, and lower by 32.1 ± 4.6% (P < 0.001) in patients with III type.

The lowest osteoregenerative activity occurred at the beginning of treatment of patients with generalized periodontal disease of III type, which followed systemic involutory osteoporosis. Therefore, the activity of bone alkaline phosphatase decreased by 21.8 ± 4.0% compared to the control; tartrate-resistant acid phosphatase (TRAP) and bone alkaline phosphatase in the blood serum.

The most representative indicator of the inflammatory-destructive process in periodontal disease is decrease in bone mineral density in the alveolar part of jaw bones. This parameter decreases in patients with II type of severity by 13.4 ± 3.2% compared to the control, and in patients with III type by 20.1 ± 3.5% (P < 0.05). Systemic osteopenic phenomena cause even greater decrease in this parameter to values which in patients with generalized periodontosis of III type of severity were 24.0 ± 4.1% lower than the control level, and lower by 32.1 ± 4.6% (P < 0.001) in patients with III type.

The lowest osteoregenerative activity occurred at the beginning of treatment of patients with generalized periodontal disease of III type, which followed systemic involutory osteoporosis. Therefore, the activity of bone alkaline phosphatase decreased by 21.8 ± 4.0% compared to the control; tartrate-resistant acid phosphatase (TRAP) and bone alkaline phosphatase in the blood serum.

The most representative indicator of the inflammatory-destructive process in periodontal disease is decrease in bone mineral density in the alveolar part of jaw bones. This parameter decreases in patients with II type of severity by 13.4 ± 3.2% compared to the control, and in patients with III type by 20.1 ± 3.5% (P < 0.05). Systemic osteopenic phenomena cause even greater decrease in this parameter to values which in patients with generalized periodontosis of III type of severity were 24.0 ± 4.1% lower than the control level, and lower by 32.1 ± 4.6% (P < 0.001) in patients with III type.

The lowest osteoregenerative activity occurred at the beginning of treatment of patients with generalized periodontal disease of III type, which followed systemic involutory osteoporosis. Therefore, the activity of bone alkaline phosphatase decreased by 21.8 ± 4.0% compared to the control; tartrate-resistant acid phosphatase (TRAP) and bone alkaline phosphatase in the blood serum.

The most representative indicator of the inflammatory-destructive process in periodontal disease is decrease in bone mineral density in the alveolar part of jaw bones.
