(Dated: November 30, 2012)

We develop a boundary field theory approach to electron spin resonance in open $S = 1/2$ Heisenberg antiferromagnetic chains with an effective staggered field. In terms of the sine Gordon effective field theory with boundaries, we point out the existence of boundary bound states of elementary excitations, and modification of the selection rules at the boundary. We argue that several "unknown modes" found in electron spin resonance experiments on KCuGaF$_6$ [I. Umegaki et al., Phys. Rev. B 79, 184401 (2009)] and Cu-PM [S. A. Zvyagin et al., Phys. Rev. Lett. 93, 027201 (2004)] can be understood as boundary resonances introduced by these effects.

Introduction. — Impurities often introduce new aspects in physics, Kondo effect being a notable example. In particular, impurity effects in strongly correlated systems are currently among central topics in condensed matter physics. Although the standard perturbation theory can fail, there are number of powerful theoretical approaches to strongly correlated systems, especially in one dimension. Impurity effects in gapless one-dimensional systems have been vigorously studied in terms of boundary conformal field theory. In contrast, impurity effects in gapped one-dimensional systems received much less attention, with the exception of the edge states in the $S = 1$ Haldane gap phase [1–3].

On the other hand, integrable models and field theories have been successfully applied to many gapped one-dimensional systems. In quantum magnetism, a field-induced gap in $S = 1/2$ Heisenberg antiferromagnetic (HAFM) chains is described in terms of a quantum sine Gordon field theory [4–6]; the one-dimensional Ising chain with critical transverse field and a weak longitudinal field realizes a quantum field theory with $E_8$ symmetry [7, 8]. Experimental studies indeed found elementary excitations predicted by these integrable field theories. Application of integrable field theories to impurity/boundary effects in gapped one-dimensional strongly correlated systems is an interesting but largely unexplored subject.

In this Letter, we present a theory of electron spin resonance (ESR) in $S = 1/2$ HAFM chains in a staggered field with boundaries, which may be realized by nonmagnetic impurities. The low-energy effective theory of the system is the quantum sine Gordon field theory with boundaries. In fact, this theory is integrable even in the presence of a boundary, and boundary bound states (BBS) of elementary excitations have been found in the exact solution [9–14]. The existence of BBS, and modification of the selection rules, imply extra resonances in addition to those in the bulk. ESR measurements on corresponding systems KCuGaF$_6$ [15] and [PM-Cu(NO$_3$)$_2$(H$_2$O)$_2$]$_n$ (PM denotes pyrimidine, abbreviated as Cu-PM) [16, 17] had found several resonances that could not be accounted for by the theory. We argue that several of those resonances can be successfully identified in terms of the boundary sine Gordon field theory.

Boundary sine-Gordon field theory. — We consider a semiopen chain with the Hamiltonian

$$\mathcal{H} = \sum_{j<0} [JS_j \cdot S_{j-1} - \mu_B H \cdot g \cdot S_j + (-1)^j \mathbf{D} \cdot S_j \times S_{j-1}],$$

which models one side of an infinite chain broken by a nonmagnetic impurity at $j = 0$. $g$ is the $g$ tensor of localized spins, and $\mu_B$ is Bohr magneton.

The Zeeman energy can be represented as $-\mu_B \sum_{j,a,b} H^a g^a_{ab} S_j^b$. Hereafter, we assume that $g^s_{ab} \ll g$, and employ a unit $h = k_B = g \mu_B = 1$.

We consider $\mathbf{H} = H \hat{z}$ applied along the $z$ direction ($\hat{z}$ is a unit vector in the $z$ direction). The last term of (1) is the staggered Dzyaloshinskii-Moriya (DM) interaction. This can be eliminated by a staggered rotation of spin about the direction of $\mathbf{D}$ by angle $(-1)^j \alpha/2$, where $\alpha = \tan^{-1}(|\mathbf{D}|/J)$ where $j$ is the site index.

Under an applied field, this transformation leaves a staggered field $h = H \times D/2$, which is perpendicular to $\mathbf{H}$ and to $\mathbf{D}$. Together with the staggered field due to the staggered component of the $g$ tensor, the effective model may be given by

$$\mathcal{H} = \sum_{j<0} [JS_j \cdot S_{j-1} - HS_j^z - h(-1)^j S_j^x],$$

keeping only the most important terms. $h = c_s H$ is the effective staggered field, approximately perpendicular to the applied field; the direction of the staggered field is chosen to be the $x$ axis. $c_s$ depends both on the staggered DM interaction and on the staggered part of $g$ tensor $g^s_{ab}$.
Using bosonization formulas, 
\[
S^\pm_x \sim m + \frac{1}{2\pi R} \partial_x \phi + C^z_s (-1)^x \cos(\phi/R + H x), \\
S^\pm_z \sim e^{\pm 2\pi R i \phi} [C^z_s (-1)^x + C^\pm_u \cos(\phi/R + H x)],
\]
for low temperature \(T \ll J\), the model (2) is mapped to a boundary sine Gordon (BSG) field theory, defined by the action 
\[
A = \int_{-\infty}^{\infty} dt \int_{-\infty}^{0} dx \left[ \frac{1}{2} \left( \frac{1}{v^2} (\partial_t \hat{\phi})^2 - (\partial_x \hat{\phi})^2 \right) \\
- C^+_x h \cos(2\pi R \hat{\phi}) \right].
\]

\(v\) is the spin-wave velocity. The fields \(\phi\) and \(\hat{\phi}\) are dual and compactified as \(\phi \sim \phi + 2\pi R\) and \(\hat{\phi} \sim \hat{\phi} + 1/R\); \(m\) is the uniform magnetization density and the nonuniversal constants \(C^z_{u,s}\) and \(C^\pm_{u,s}\) are determined numerically [18]. The bulk operator \(\cos(2\pi R \hat{\phi})\), which represents the transverse staggered magnetization, is relevant in the renormalization group sense. Thus it induces a finite mass (excitation gap), as it was observed in the experiments. [5, 6] The bulk gap is stable against dilute nonmagnetic impurities.

In the absence of the staggered field term, the field \(\phi\) obeys the Dirichlet boundary condition \(\phi(x = 0, t) = \text{const.}\). This is equivalent to the Neumann boundary condition in terms of the dual field:
\[
\partial_x \hat{\phi}(x, t) \bigg|_{x=0} = 0.
\]

Inclusion of the staggered field could change the boundary condition; in fact, the staggered field in the bulk would also induce the corresponding operator \(\cos(2\pi R \hat{\phi})\) at the boundary. If this boundary perturbation is dominant, \(\hat{\phi}\) would obey the Dirichlet boundary condition. However, since \(\cos(2\pi R \hat{\phi})\) is, as a boundary operator, (nearly) marginal in RG, its effects are negligible at the energy scale set by the bulk spin gap. Thus, for a small staggered field \(h\), the boundary condition can still be regarded as the Neumann on \(\phi\).

Energy spectrum. — The elementary excitation of the bulk sine Gordon field theory includes soliton (denoted by \(S\)) and antisoliton (\(\bar{S}\)) with the same mass \(M\). A soliton and antisoliton carry soliton charge \(Q = +1\) and \(Q = -1\), respectively. Additional particles called breathers are generated as bound states of a soliton and an antisoliton [20, 21]. There can be several different kinds of breathers \(B_n\) with the mass \(M_n = 2M \sin(n\pi \xi/2)\), for \(n = 1, 2, \ldots, \lfloor \xi^{-1} \rfloor\). Here \(\lfloor \cdot \rfloor\) is the floor function. Breathers have zero soliton charge. The soliton charge is conserved in the bulk sine Gordon field theory. For the case of our interest, that is experimental situations in KCuGaF\(_6\) and Cu-PM, the parameter \(\xi = 1/(2/\pi R^2 - 1)\) satisfies \(\xi < 1/3\). In particular, \(\xi \approx 1/3\) in the low field limit \(H \to 0\).

Fortunately, the BSG theory (5) with the Neumann boundary condition (6) is still integrable [9]. An analysis of the boundary \(S\) matrices implies [9–12, 22] the existence of the BBS with the mass
\[
M_{\text{BBS}} = M \sin(\pi \xi),
\]
for \(\xi < 1/2\). Therefore, the BBS with \(M_{\text{BBS}} \sim \sqrt{\frac{3}{2}}M/2\) does exist in the low field limit of the present system. The BBS of soliton, antisoliton, and first breather turn out to be identical and there is only one type of BBS. This is another manifestation of the soliton charge nonconservation at the boundary.

Thus the analysis of the BSG theory predicts a new excited state, which is a BBS, at the energy \(M_{\text{BBS}}\) lower than the bulk gap \(M\). In fact, in an earlier numerical study of an open chain based on density matrix renormalization group, Lou et al. [23, 24] had found such an excited state localized near the boundary. They called it a midgap state.

Figure 1 shows a comparison of the soliton (12) and BBS (7) masses, to the numerically obtained bulk gap and the energy of the midgap state in Refs. [23, 24]. Here we used \(M \approx 1.85(h/J)^{2/3} [\ln(h/J)]^{1/6}\) appropriate for \(H = 0\), which was used in Refs. [23, 24]. The excellent agreement between the two energies means that the midgap state found in the DMRG calculation was nothing but a BBS.

While it was pointed out in Refs. [23, 24] that the midgap state is localized near the boundary, physical understanding of its origin has been lacking. The analogy to the edge state in the Haldane phase is clearly inappropriate, since the \(S = 1/2\) HAFM in a staggered field is topologically trivial. With the present identification of the midgap state with the BBS, the BSG theory is established as an effective theory describing the boundary physics of the system. This is essential in understanding the ESR spectra.

Electron spin resonance. — Next we discuss the ESR spectrum, which is given by \(I(\omega) \propto \omega \chi''(q = 0, \omega)\). Here, \(\chi''\) is an imaginary part of the dynamical susceptibility \(\chi\). \(\chi_{+-}(q, \omega) = -G_{S-S-}(q, i\omega = \omega + i\epsilon)\) where positive infinitesimal \(\epsilon\) is the analytic continuation of the
temperature Green’s function $G_{S+S_{\perp}}(q, i\omega)$. The staggered rotation of spins by angles $(-1)^j \alpha/2$ to eliminate the DM interaction mix the uniform ($q = 0$) and the staggered ($q = \pi$) components. The physical susceptibility $\chi''_{\text{phys}}(q = 0, \omega)$ is

$$\chi''_{\text{phys}}(0, \omega) \sim \chi_{++}''(0, \omega) + \left( \frac{D_z}{J} \right)^2 \chi_{++}''(\pi, \omega), \quad (8)$$

where $D_z$ is the $z$ component of the DM vector $\mathbf{D}$ parallel to the applied field. On the right-hand side, we dropped the longitudinal susceptibility $\chi_{zz}(q = \pi, \omega)$ because it contains the same resonances as those in the transverse part $\chi_{+-}(q = 0, \omega)$, and merely modifies their intensities.

Let us first review the ESR in the bulk, in the limit of $T \to 0$. The uniform part $\chi_{++}''(0, \omega)$ reflects transitions caused by the operator

$$S_{q=0}^\pm \sim e^{\pm 2\pi Ri\phi} \cos(\phi/R + Hx). \quad (9)$$

The operator $\cos(\phi/R)$ changes the soliton charge by $\pm 1$, and thus must create at least one soliton or antisoliton. The other factor $e^{\pm 2\pi Ri\phi}$ can create any number of excitations with zero soliton charge in total. Thus ESR induced by the operator (9) with the lowest possible energy corresponds to creation of a single soliton or antisoliton. It should be also noted that the factor $Hx$ in the cosine causes the shift of the momentum with $H$. That is, the created soliton or antisoliton should carry the momentum $H$. Thus the ESR due to a single soliton/antisoliton creation is at frequency $\omega = E_S = \sqrt{M^2 + H^2}$. There are also resonances due to (9) at higher energies, corresponding to creation of additional elementary excitations.

Next we turn to the staggered part $\chi_{+-}''(q = \pi, \omega)$, which reflects transitions caused by the operator

$$S_{q=\pi}^\pm \sim e^{\pm 2\pi Ri\phi}. \quad (10)$$

This carries zero soliton charge, and thus the simplest excitation induced by this operator is creation of a single breather $B_n$. This leads to the resonances at $\omega = M_n$.

Now let us discuss the boundary effects on ESR. Here we discuss the ESR spectrum based on physical picture, leaving systematic formulations to the Supplementary Material.

First we consider the contribution of the staggered part $\chi_{+-}''(q = \pi, \omega)$. The simplest excitation created by the operator (10) is a single breather. In the presence of the boundary, the first breather can form the BBS. Thus the resonance with the lowest energy in the presence of the boundary is given by $\omega = M_{\text{BBS}}$. Creation of a breather not bounded at the boundary and the BBS is also possible, leading to the resonance at $\omega = M_{\text{BBS}} + M_n$.

In order to understand the boundary effects on ESR, we need to clarify the issue of the momentum conservation. In general, total momentum is conserved due to the translation invariance of the system. In the presence of the boundary, the translation invariance is lost and the total momentum is no longer conserved. Nevertheless, the momentum is still important in discussing ESR spectra, because the momentum of each elementary excitation is conserved or reversed in a scattering with another elementary excitation, or in a reflection at the boundary. Thus, once created, the set of momenta of elementary excitations is conserved, up to the sign of each momentum.

The existence of the boundary has an interesting effect, in addition to the contribution of the BBS, on the ESR spectrum. Although the expectation of the operator $\cos(\phi/R)$ vanishes in the bulk, it is nonvanishing [25, 26] near a boundary with the Dirichlet boundary condition on $\phi$ (equivalent to the Neumann boundary condition (6) on $\phi$). This reflects $\phi$ taking a fixed value at the boundary. Thus, in the vicinity of the boundary, the leading contribution from the uniform part is effectively given by the operator $S_{q=0}^\pm \sim e^{\pm 2\pi Ri\phi} \cos(\phi/R + Hx)$, which creates excitations with zero soliton charge, in contrast to the original one (9). This is another consequence of violation of soliton charge conservation at the boundary. The created excitations should carry the total momentum $\pm H$, up to the uncertainty $\sim 1/l_p$. Here $l_p$ is the pinning lengths cale, namely $\phi(x) \sim \text{const.}$ if $|x| < l_p$.

Thus, the simplest among the possible ESR processes due to this operator is the creation of a single breather $B_n$ with momentum $\pm H$. This corresponds to the frequency

$$E_n = \sqrt{M_n^2 + H^2}. \quad (11)$$

The resonance at $E_n$ with $n > 1$ was absent in the bulk and is a new feature due to the boundary. We emphasize that, these new resonances do not simply follow from

| $T = 0$ | $T > 0$ |
|---|---|
| $\omega = E_S, E_S + M_n, E_S + M_{\text{BBS}}, E_n + M_{\text{BBS}}$ | $\omega = M_{\text{BBS}} - M_n, (n > m)$ |

Table I. Typical resonance modes in $\chi_{+-}''(q = 0, \omega)$. Resonances shown in the second row are absent at $T = 0$. The soliton resonance $E_S$ is accompanied with all bulk resonances. On the other hand, $E_S$ does not necessarily appear in the boundary resonances. In fact, some boundary resonances are involved with a novel resonance $E_n$ instead of $E_S$. In the presence of the boundary, the translation invariance is lost and the total momentum is no longer conserved. Nevertheless, the momentum is still important in discussing ESR spectra, because the momentum of each elementary excitation is conserved or reversed in a scattering with another elementary excitation, or in a reflection at the boundary. Thus, once created, the set of momenta of elementary excitations is conserved, up to the sign of each momentum.

The existence of the boundary has an interesting effect, in addition to the contribution of the BBS, on the ESR spectrum. Although the expectation of the operator $\cos(\phi/R)$ vanishes in the bulk, it is nonvanishing near a boundary with the Dirichlet boundary condition on $\phi$ (equivalent to the Neumann boundary condition on $\phi$). This reflects $\phi$ taking a fixed value at the boundary. Thus, in the vicinity of the boundary, the leading contribution from the uniform part is effectively given by the operator $S_{q=0}^\pm \sim e^{\pm 2\pi Ri\phi} \cos(\phi/R + Hx)$, which creates excitations with zero soliton charge, in contrast to the original one (9). This is another consequence of violation of soliton charge conservation at the boundary. The created excitations should carry the total momentum $\pm H$, up to the uncertainty $\sim 1/l_p$. Here $l_p$ is the pinning lengths cale, namely $\phi(x) \sim \text{const.}$ if $|x| < l_p$.

Thus, the simplest among the possible ESR processes due to this operator is the creation of a single breather $B_n$ with momentum $\pm H$. This corresponds to the frequency

$$E_n = \sqrt{M_n^2 + H^2}. \quad (11)$$

The resonance at $E_n$ with $n > 1$ was absent in the bulk and is a new feature due to the boundary. We emphasize that, these new resonances do not simply follow from

| $T = 0$ | $T > 0$ |
|---|---|
| $\omega = E_S, E_S + M_n, E_S + M_{\text{BBS}}, E_n + M_{\text{BBS}}$ | $\omega = M_{\text{BBS}} - M_n, (n > m)$ |

Table II. Typical resonance modes in $\chi_{+-}''(q = \pi, \omega)$. Breather masses are directly measured in the bulk part. The BBS mass itself appears in the boundary resonances. Equations (8) shows that intensities of these modes are smaller than those in Table 1 by $(D_z/J)^2$.
the existence of the midgap state numerically found in Refs. [23, 24]. In fact, the resonance frequency $E_n$ does not explicitly contain the energy $M_{BBS}$. This shows the necessity of the BSG framework to fully understand the physics at the boundary.

At finite temperatures, additional resonances may be observable. When the initial state contains the BBS as a thermal excitation, a resonance at $\omega = M_n - M_{BBS}$ exists, corresponding to annihilation of the BBS and creation of a breather $B_n$. Similarly, when the initial state contains $B_1$, the resonance at $\omega = M_n - M_1 + M_{BBS}$ corresponds to the creation of $B_n$ and binding of $B_1$ at the boundary. These resonances are contained in the staggered part $\chi''_{n+}(\pi, \omega)$. The uniform part also contains, at finite temperatures, additional resonances.

Typical resonance modes are summarized in Tables I and II. Note that intensities of resonances due to the staggered part $\chi''_{n+}(q = \pi, \omega)$ and $\chi''_{zz}(q = \pi, \omega)$ are suppressed by the factor $(D_2/J)^2$ in (8), compared to those from the uniform part $\chi''_{n+}(q = 0, \pi)$.

Comparison with experiments. — Thus several novel resonances, which are absent in the bulk, are derived from the BSG theory. They indeed match the “unknown” resonances observed previously in ESR spectra on KCuGaF$_6$ (Figures 2) and Cu-PM (Figure 3). Here the uniform field effect is taken into account in the soliton-antisoliton mass [27],

$$M = \frac{2v \Gamma(\xi/2)}{\sqrt{\pi} \Gamma((1 + \xi)/2)} \left[ \frac{\Gamma(1/(1 + \xi))}{\Gamma(\xi/(1 + \xi))} \right] \frac{C_2^* \pi}{2v c_s H} \right]^{(1+\xi)/2}.$$

While the ratio $c_s = h/H$ can in principle be determined by the staggered DM interaction and $g$ tensor, we use the value obtained by fitting experimental data.

Each figure shows different resonances, though. The difference between the spectra in two materials can be understood in terms of the different magnitude of the DM interaction. The coefficient $c_s$ at its maximum is larger (0.178) in KCuGaF$_6$ compared to 0.083 in Cu-PM. While precise estimates of the DM interaction and the staggered $g$ tensor are not available, the staggered DM interaction is presumably larger in KCuGaF$_6$. This leads to larger mixing of the staggered part $\chi''_{n+}(q = \pi, \omega)$. Thus it is natural that the resonances due to the mixings are observed only in KCuGaF$_6$ (Fig. 2). We note that, the simplest possible BBS contribution at $\omega = M_{BBS}$ is not observed for $H \parallel a$ in Fig. 2 (a). This is presumably because only two of the frequencies used in the experiments can detect the resonance below the bulk resonance at $\omega = M_1$. On the other hand, in the Cu-PM with a smaller DM interaction, only the contributions from the

![Figure 2](image1.png)

Figure 2. (color online) Frequency vs field diagrams of ESR in KCuGaF$_6$ [15] for (a) $H \parallel a$ and (b) $H \parallel c$ configurations. The dotted line is high temperature paramagnetic resonance $\omega = H$. Open symbols and filled symbols represent bulk modes and “unknown modes.” $E_1, B_1, B_2, B_3$ denotes resonances $\omega = E_S, M_1, M_2, M_3$ by a soliton $S$ and breathers $B_n$. An antisoliton $\bar{S}$ also leads to $\omega = E_S$. The labels $U_1, U_2, U_3$ are “unknown” peaks found in [15]. (a) The configuration $H \parallel a$ bears the smallest $h = c_s H$ with the coefficient $c_s = 0.031$. An excitation $\omega = M_1 + M_{BBS}$ is found in addition to the bulk excitations. (b) We have the largest staggered field, $c_s = 0.178$, when $H \parallel c$. This large $c_s$ makes the rich kinds of boundary modes detectable. The labels BB, 2*B$_{BB}$, B$_{2}$-B$_{1}$+BB denote $\omega = M_{BBS}, 2M_1 - M_{BBS}, M_2 - M_1 + M_{BBS}$.

![Figure 3](image2.png)

Figure 3. (color online) Frequency vs field diagrams of ESR in Cu-PM [16]. Two “unknown” peaks $U_1$ and $U_2$ are attributed to $\omega = E_2$, $E_1 + M_1 - M_{BBS}$ respectively, where $E_n$ is defined in Eq.(11). These boundary modes appear in $\chi''_{zz}(q = 0, \omega)$. 

4
uniform part are observed (Fig. 3). We conjecture that, with more careful examination of the spectra, more resonances due to the BBS will be found in experiments.

Conclusions. — We point out the existence of BBS and modification of the selection rules at boundaries of the $S = 1/2$ antiferromagnetic chain in an effective staggered field, in terms of the BSG theory (5). The boundary effects can account for the mysterious “unknown modes” found in two compounds KCuGaF$_6$ [15] and Cu-PM [16, 17].

In the compound KCuGaF$_6$, magnetic ions Cu$^{2+}$ and nonmagnetic ions Ga$^{3+}$ form a pyrochlore lattice. Magnetically, the compound KCuGaF$_6$ is effectively regarded as $S = 1/2$ HAFM chains of Cu$^{2+}$ ions. However, since Cu$^{2+}$ and Ga$^{3+}$ ions occupy equivalent positions, an intersite mixing of them can occur in the course of syntheses [28]. We speculate that the intersite mixing brings about nonmagnetic impurities in spin chains. We expect that a few percent of the nonmagnetic impurities would lead to observation of the boundary resonances as discussed in this Letter. Our picture may be verified experimentally by controlling the density of nonmagnetic impurity, which will change the intensity of boundary resonances.

The authors thank P. Bouillot, T. Giamarchi, S. Takayoshi, H. Tanaka, I. Umegaki, and S. Zvyagin for fruitful discussions. This work is partly supported by the Global COE Program “The Physical Sciences Frontier” (S.C.F.), and KAKENHI Grant No. 50262043 from MEXT of Japan.

EFFECTIVE LATTICE MODEL

\[ H = J \sum_j S_j \cdot S_{j-1} - h S_j^z + (-1)^j D \cdot S_j \times S_{j-1} \].

Here, for simplicity, the effects of the anisotropic tensor are ignored, and they will be taken into account later. We rotate the spin \( S_j \) about the direction of \( D \) by the angle \( (-1)^j \alpha / 2 \) where \( \alpha = \tan^{-1}(|D|/J) \). When \( |D| \ll J \), \( \alpha \ll 1 \) and the transformation of the spin operator can be linearized as

\[ S_j \rightarrow S_j + (-1)^j \frac{D}{2J} \times S_j. \]

Thus, in the presence of the uniform applied field \( H \), a staggered field perpendicular to both \( H \) and \( D \) is generated.

In addition, the staggered component of \( g \) tensor also contributes to generating the staggered field. In contrast to the one due to the staggered DM interaction, the staggered field coming from the staggered component of the \( g \) tensor is not necessarily perpendicular to the applied field. However, in the effective field theory description, the longitudinal component of the staggered field accompanies an oscillating factor, which makes it vanish upon spatial integration. Thus it can be ignored for the purpose of discussion of gap opening, and only the transverse staggered field has to be considered.

Therefore, the \( S = 1/2 \) antiferromagnetic chain under an applied magnetic field, with both staggered \( g \) tensor and staggered DM interaction can be described by the effective lattice model (2) of the main text. The effective staggered field \( h \) depends on both the staggered DM interaction and the staggered \( g \) tensor.

In the course of eliminating the staggered DM interaction, the spin operator is transformed according to Eq. (14). This has to be taken into account in the discussion of physical susceptibility. Namely, the physical uniform susceptibility \( \chi''(q = 0, \omega) \) has contributions from both uniform and staggered susceptibilities calculated for the effective model after the elimination of the DM interaction:

\[ \chi''(q = 0, \omega) \sim \chi_{\perp -}(q = 0, \omega) + \left( \frac{D_\perp}{J} \right)^2 \chi_{\perp -}(q = \pi, \omega) + \left( \frac{D_\perp}{J} \right)^2 \chi''(q = \pi, \omega), \]

where \( D_\perp \) is the magnitude of the component \( D \) perpendicular to the \( z \) axis. As we will see below, the longitudinal susceptibility \( \chi''(q = \pi, \omega) \) adds no resonant peak to the former two susceptibilities. The longitudinal staggered susceptibility just modifies intensities of the transverse susceptibilities.

Fig. 4 shows a schematic picture of the staggered fields generated from the external uniform field \( H \), in the bulk \((h)\) and at the boundary \((h_B)\). Note that the boundary staggered field \( h_B \), coupled to the end spin \( S_0^z \), is indistinguishable to the bulk staggered field \( h \) in the lattice model. But their behaviors under renormalization group (RG) transformations are quite different.

RG ANALYSIS

The bosonization of spins leads to an effective boundary field theory with an action,

\[ A = \int_{-\infty}^{\infty} dt \int_{0}^{\theta} dx \left[ \frac{1}{2} \left\{ \frac{1}{2} (\partial^2 \hat{\phi})^2 - (\partial_x \hat{\phi})^2 \right\} - C_s^1 h \cos(2\pi R \hat{\phi}) \right] - C_s^1 h_B \int_{-\infty}^{\infty} dt \cos(2\pi R \hat{\phi}(x = 0)). \]

Scaling dimensions of the bulk and boundary staggered magnetizations are respectively

\[ x_h = \pi R^2, \quad x_{h_B} = 2\pi R^2. \]

When the uniform field \( H \) is zero, the effective lattice model (2) in the paper is SU(2) symmetric, where the compactification radius \( R \) is given by \( R = 1/\sqrt{2\pi} \). As the uniform and staggered fields increase, the compactification radius decreases [1]. Recall that a bulk operator is relevant (irrelevant) when its scaling dimension is smaller (bigger) than 2, and a boundary operator is relevant (irrelevant) when its scaling dimension is smaller (bigger) than 1. Thus, both the bulk \((x_h \leq 1/2)\) and
boundary \( x_{h_B} \leq 1 \) staggered magnetizations are relevant. The boundary staggered magnetization is marginal at zero field \( H = 0 \). The boundary RG flow is shown in Fig. 5. The line \( h_B = 0 \) corresponds to the Neumann boundary condition. In the presence of the boundary staggered field, the boundary condition is neither Neumann nor Dirichlet:

\[
\partial_x \tilde{\phi}(x,t) \bigg|_{x=0} = 2\pi R C^+ \tilde{h}_B \sin \left[2\pi R \tilde{\phi}(x = 0, t) \right]
\]

\( h_B = +\infty \) corresponds to the Dirichlet boundary condition because the field \( \tilde{\phi}(x = 0, t) \) is pinned to a certain value in order to optimize the potential energy \( \propto h_B \cos [2\pi R \tilde{\phi}(x = 0, t)] \).

As we perform the RG transformation iteratively, the bulk staggered field \( h \) grows rapidly. When the effective coupling \( h/J \) becomes \( O(1) \), the RG transformation breaks down. On the other hand, the boundary staggered field \( h_B/J \) is still much smaller than 1 after the iterative RG transformations because the boundary staggered magnetization is almost marginal. Therefore, at the lowest order approximation, we may ignore the boundary staggered field \( h \). Finally we reach the effective action of the boundary sine Gordon model (5) together with the boundary condition (6), in the main text.

**BOUNDARY BOUND STATE**

Here, following Refs. [2, 3], we briefly review the energy spectrum of the boundary sine Gordon model with the Neumann condition. The energy spectrum in bulk is the same as those in the conventional sine Gordon model. A soliton (denoted as \( S \)) and an antisoliton (denoted as \( \bar{S} \)) exist and several breathers are formed as bound states of one soliton and one antisoliton. One can know that masses of breathers by analyzing simple poles of the exact \( S \) matrix. As is well known, the \( S \) matrix characterizes two-particle scatterings:

\[
\begin{align*}
Z_{a_1} (\theta_1) Z_{a_2} (\theta_2) &= S_{a_1 a_2} (\theta_1 - \theta_2) Z_{b_1} (\theta_2) Z_{b_1} (\theta_1) \\
Z_{a_1}^{\dagger} (\theta_1) Z_{a_2}^{\dagger} (\theta_2) &= S_{a_2 a_1} (\theta_1 - \theta_2) Z_{b_1}^{\dagger} (\theta_2) Z_{b_1}^{\dagger} (\theta_1) \\
Z_{a_1} (\theta_1) Z_{a_2}^{\dagger} (\theta_2) &= 2\pi \delta_{a_1 a_2} \delta(\theta_1 - \theta_2) + S_{a_2 a_1} (\theta_1 - \theta_2) Z_{b_1}^{\dagger} (\theta_2) Z_{b_1} (\theta_1)
\end{align*}
\]

Operators \( Z_a (\theta) \) and \( Z_a^{\dagger} (\theta) \) are called as Faddeev-Zamolodchikov (FZ) operators. The parameter \( \theta \) is called as a rapidity, which parameterize the energy \( E_a \) and the momentum \( P_a \) of a particle with an index \( a \) as

\[
E_a (\theta) = M_a \cosh \theta, \quad P_a (\theta) = M_a \sinh \theta.
\]

Since every scattering in integrable field theories is factorizable to several two-particle scatterings, the \( S \) matrix determines whole energy spectrum in bulk. An \( n \)-th breather has a mass,

\[
M_n = 2M \sin \left(\frac{n\pi \xi}{2}\right),
\]

for \( n = 1, 2, \cdots, |\xi^{-1}| \). Since breathers are formed by a soliton and an antisoliton with the degenerate mass \( M \), the mass of the breather \( M_n \) is smaller than \( 2M \).

Similar procedure is applicable to investigate the energy spectrum at the boundary. The scattering at the boundary is shown in Fig. 6 (a). The spatial boundary is regarded as an infinitely heavy particle \( B \).

\[
Z_{a_1} (\theta_1) B = R_B^b (\theta) Z_{a_1}^{\dagger} (\theta) B
\]

The index \( \bar{a} \) represents the anti-particle of the particle \( a \). The reflection factor \( R_B^b (\theta) \) has been studied in detail [3]. Simple poles of the reflection factor \( R_B^b (\theta) \) represents energy levels localized at the boundary, called as a boundary bound state (BBS).

For later convenience, we consider a rotated reflection factor

\[
R^{ab} (\theta) \equiv R_B^b \left( -\frac{i\pi}{2} - \theta \right).
\]
According to Ref. [3], the rotated reflection factor \( K^{ab}(\theta) \) has the following simple poles \( \theta = iu_{ab} \) within the physical strip \( 0 < \text{Im} \theta < \pi/2 \),

\[
    u_{ab} = u_{SS} \equiv \frac{\pi \xi}{2} , \quad (a, b = S, \bar{S})
\]

\[
    u_{ab} = u_{B_1 B_1} \equiv \frac{\pi - \pi \xi}{2} , \quad (a = b = B_1).
\]

(22)

(23)

Here we assumed the experimentally realized situation \( 3 < \xi^{-1} < 4 \). Both poles (22) and (23) lead to the same BBS. In fact, the excitation gap of the BBS, \( M_{BBS} \), is derived by the following two manners.

1. One soliton \( S \) or one antisoliton \( \bar{S} \) forms a BBS:

\[
    M_{BBS} = M \sin u_{SS} = M \sin(\pi \xi).
\]

2. One first breather \( B_1 \) forms a BBS:

\[
    M_{BBS} = M_1 \sin u_{B_1 B_1} = M \sin(\pi \xi).
\]

(24)

(25)

In (25), we used the relation (19). The formation of a BBS is sketched in Fig. 6 (b). Note that the BBS is formed by a soliton with the mass \( M \) or by a first breather with the mass \( M_1 \). The mass of the BBS should be smaller than \( \min{\{M, M_1\}} \). Since \( \min{\{M, M_1\}} \) is the lowest excitation gap, the BBS appears below the bulk gap.

**CORRELATION FUNCTIONS**

We summarize correlation functions in the presence of the boundary. In the Euclidean space, a two-point correlation function \( G_{S^+ S^-}(x_1, x_2, \tau) \) depends on two spatial variables \( x_1 \) and \( x_2 \) because the translational symmetry is broken by the boundary (impurity). For a systematic treatment, it is useful to make a Wick rotation to regard the spatial variable \( x \) as the “time”, and \( \tau \) as the “space” variable. In this framework,

\[
    G_{S^+ S^-}(x_1, x_2, \tau) = \frac{\langle \text{vac}|T_\tau S^+(x_1, \tau)S^-(x_2, 0)|\text{B}\rangle}{\langle \text{vac}|\text{B}\rangle}.
\]

(26)

The state \( |\text{vac}\rangle \) is the ground state (with length given by the inverse temperature of the original system, and with the periodic boundary conditions). The symbol \( T_\tau \) denotes the \( x \) ordering, that is, the ordering which orders operators with larger \( x_i \) to right. Note that the spin \( S^a(x, \tau) \) is related to \( S^a(0, 0) \) via

\[
    S^a(x, \tau) = e^{-x E} e^{-i \pi P} S^a(0, 0) e^{i \pi P} e^{x P},
\]

where \( E \) and \( P \) are the total energy and the total momentum respectively. The state \( |\text{B}\rangle \) is called as a boundary state written in FZ operators and the rotated reflection factor [2].

\[
    |\text{B}\rangle = e^K|\text{vac}\rangle = \exp\left[ \frac{1}{2} \sum_{a,b} \int_{-\infty}^{\infty} \frac{d\theta}{2\pi} K^{ab}(\theta)Z^+_a(-\theta)Z_b^+(\theta) \right]|\text{vac}\rangle.
\]

(27)

The Fourier transform of the \( x \)-ordered correlation function is given by

\[
    G_{S^+ S^-}(q, i\omega) = \frac{1}{N} \int_0^\infty d\tau \int_{-\infty}^\infty d\sigma X e^{i(\omega \tau - q \sigma)} G_{S^+ S^-}(x_1, x_2, \tau).
\]

(28)

where \( \bar{\omega} \) is the Matsubara frequency. Instead of spatial variables \( x_1 \) and \( x_2 \), we used \( r = -|x_1 - x_2| \) and \( X = (x_1 + x_2)/2 \). The infinitely large \( N \) represents the length of the semi-infinite spin chain and the coefficient \( 1/N \) can be understood as a density of non-magnetic impurities. When we compute dynamical susceptibility, we perform the analytic continuation \( i\omega \rightarrow \omega + i\epsilon \), where \( \epsilon \) is positive infinitesimal.

**BULK RESONANCES**

Here we derive several resonant peaks in the ESR spectrum. An \( n \)-particle state \( |\theta_1, \theta_2, \cdots, \theta_n, a_1, a_2, \cdots a_n\rangle \) and its conjugate \( a_n \cdots a_1 |\theta_1, \cdots, \theta_n\rangle \) are parameterized by the single parameter \( \theta \). Where we put \( v = 1 \) for simplicity. The above multi-particle states are orthonormal.

\[
    a_n \cdots a_1 |\theta_1, \cdots, \theta_n\rangle |\theta_1', \cdots, \theta_n'\rangle = \delta_{\theta_1 \theta_1'} \cdots \delta_{\theta_n \theta_n'}
\]

(29)

A set of \( n \)-particle states is complete:

\[
    1 = |\text{vac}\rangle \langle \text{vac}| + \sum_{n=1}^\infty \frac{1}{n!} \sum_{a_1, \cdots, a_n} \int \frac{d\theta_1 \cdots d\theta_n}{(2\pi)^n} |\theta_1, \cdots, \theta_n\rangle a_1 \cdots a_n a_n \cdots a_1 |\theta_1, \cdots, \theta_n\rangle.
\]

(30)
This identity operator allows one to expand correlation functions by intermediate states. We can expand the boundary state in the power of $K$ as

$$|B\rangle = e^K|\text{vac}\rangle = |\text{vac}\rangle + K|\text{vac}\rangle + \cdots .$$  \hfill (31)

Let us consider the bulk part of the correlation $G_{S+S-}(q = \pi, i\omega)$, that is,

$$G_{S+S-}^{(0)}(q = \pi, i\omega) = \frac{1}{N} C_s \int_0^\infty d\tau \int_0^\infty d\tilde{\tau} \int_{-\infty}^\infty dX e^{i\tilde{\omega}\tau} \langle \text{vac}|T_x e^{-i2\pi R\tilde{\phi}(x,\tau)} e^{i2\pi R\tilde{\phi}(x,0)}|\text{vac}\rangle$$

$$= \sum_{m=1}^{\xi^{-1}} \frac{\pi v C_s^2}{M_m} |F_{B_m}^{e^{i2\pi R\tilde{\phi}}}|^2 \left( \frac{1}{i\tilde{\omega} - M_m} + \frac{1}{i\tilde{\omega} + M_m} \right) + \cdots .$$  \hfill (32)

Thanks to the Lorentz invariance of the sine Gordon model, the matrix element $\langle \text{vac}|e^{-i2\pi R\tilde{\phi}(x,\tau)}|\theta\rangle_B$ involving the intermediate state $|\theta\rangle_B$ can be computed easily.

$$\langle \text{vac}|e^{-i2\pi R\tilde{\phi}(x,\tau)}|\theta\rangle_B = F_{B_m}^{e^{i2\pi R\tilde{\phi}}} e^{i\pi M_m \sinh \theta + x M_m \cosh \theta}$$

The factor $F_{B_m}^{e^{i2\pi R\tilde{\phi}}}$ is a form factor of the operator $e^{-i2\pi R\tilde{\phi}}$. Form factors generally depend on the rapidity $\theta$, but the $F_{B_m}^{e^{i2\pi R\tilde{\phi}}}$ does not. In integrable field theories, form factors can be exactly derived. One can find several exact form factors of the sine Gordon model in Ref. 4.

After taking analytic continuation $i\tilde{\omega} \to \omega + i\epsilon$, we obtain

$$-\text{Im} G_{S+S-}^{(0)}(q = \pi, \omega + i\epsilon)$$

$$= \sum_{n=1}^{\xi^{-1}} 2\pi v C_s^2 |F_{B_n}^{e^{i2\pi R\tilde{\phi}}}|^2 \delta(\omega - M_n) + \cdots .$$  \hfill (33)

Multi-particle resonant peaks such as $\delta(\omega - M_n - M_m)$ exist in the ignored terms. (33) leads to peaks in (15) as

$$\left( \frac{D_z}{J} \right)^2 \sum_{n=1}^{\xi^{-1}} 2\pi v C_s^2 |F_{B_n}^{e^{i2\pi R\tilde{\phi}}}|^2 \delta(\omega - M_n) + \cdots .$$  \hfill (34)

As stated in the paper, the intensity of the staggered susceptibility $\chi''_{++}(q = \pi, \omega)$ is suppressed by the factor $(D_z / J)^2$. Bulk parts of the resonant peaks which come from $\chi''_{+-}(0,\omega)$ and $\chi''_{++}(\pi,\omega)$ are similarly obtained, which are respectively

$$\frac{\pi v C_s^2}{M} |F_S^{e^{i\pi M_0/R + i2\pi R\tilde{\phi}(0)}}(\theta_0)|^2 \delta(\omega - E_S) ,$$

$$\left( \frac{D_z}{J} \right)^2 \frac{\pi v C_s^2}{M} |F_S^{e^{i\pi M_0/R + i2\pi R\tilde{\phi}}} (\theta_0)|^2 \delta(\omega - E_S) .$$  \hfill (35, 36)

$$\theta_0 \equiv \ln \left[ \left\{ H + \sqrt{M^2 + H^2} \right\} / M \right] .$$

Both of them detect the soliton resonance at $\omega = E_S = \sqrt{M^2 + H^2}$. The latter (36) has a weaker intensity by the factor $(D_z / J)^2$ than the former (35). The $q = \pi$ component of $S_x^z$

$$S_x^z \sim C_u (-1)^z \cos(\phi/R + H x),$$

is similar to the $q = 0$ component of $S_x^z$

$$S_x^z \sim C_u e^{i\pi 2\pi R\tilde{\phi}} \cos(\phi/R + H x).$$

Thus, all resonant peaks in $\chi''_{zz}(q = \pi, \omega)$ appear also in $\chi''_{zz}(q = 0, \omega)$, and the latter has stronger intensities in (15). We may forget $\chi''_{zz}(q = \pi, \omega)$ when we focus on resonance frequencies.

We should emphasize that the breather resonances $\delta(\omega - M_n)$ can result only from the transverse staggered component $\chi''_{+-}(q = \pi, \omega)$ in $\chi''_{phys}(q = 0, \omega)$. This is an important consequence of the mixing (15) caused by the staggered DM interaction. Without the mixing, we cannot observe any breather resonance.

**BOUNDARY RESONANCES**

**Transverse staggered component $G_{S+S-}(q = \pi, i\omega)$**

Boundary scatterings induce rich amounts of additional resonances. For instance, we consider the first order contribution in the expansion (31) to the $G_{S+S-}(q = \pi, i\omega)$.
\( G_{S+S}^{(1)}(q, \pi, i\omega) \) is given by:

\[
G_{S+S}^{(1)}(q, \pi, i\omega) = \frac{1}{N} C_s^{1/2} \int_0^\infty d\tau \int_0^\infty dr dX e^{i\omega \tau} \sum_{a,b} \int_{-\infty}^\infty \frac{d\theta}{2\pi} K^{ab}(\theta) \langle \text{vac}| T_x e^{-i2\pi R\hat{o}_x(x_1, \tau)} e^{i2\pi R\hat{o}_x(x_2, 0)} | -\theta, \theta \rangle_{ab}
\]

where \( u_{S+S} \) and \( u_{B_1} \) are given by (22) and (23). The residues \(-i f_S\) and \(-i f_{B_1}\) are not derivable at the moment of publication.

The resonance frequency \( \omega \) is given by:

\[
\omega = \frac{D}{M} \left( \frac{2\pi v}{M} \right)^2 \left( \frac{1}{M_1^2 \sin(\pi \xi/2)} \right) \delta(\omega - M_{BBS})
\]

The pole \( M_1 \sin u_{B_1} - M \sin(\pi \xi) = M_{BBS} \) gives a resonance of the boundary bound state (BBS) in \( \chi''_{\text{phys}}(q = 0, \omega) \):

The pole \( M_1 \sin u_{B_1} - M \sin(\pi \xi) = M_{BBS} \) gives a resonance of the boundary bound state (BBS) in \( \chi''_{\text{phys}}(q = 0, \omega) \):

\[
\langle \text{vac}| e^{-i2\pi R\hat{o}_x(x_1, \tau)} | \theta_1, \theta_2 \rangle_{B_1 B_1} = \langle \text{vac}| e^{-i2\pi R\hat{o}_x(x_2, 0)} | -\theta, \theta \rangle_{B_1 B_1} + \cdots
\]

\( \theta_H(x) \) is the Heaviside step function. As we reviewed above, the factor \( K^{ab}(\theta) \) has simple poles in the physical strip \( 0 \leq \text{Im} \theta < \pi/2 \),

\[
\text{Res}_{\theta = u_{S+S}} K^{ab}(\theta) = -i f_S, \quad (a, b = S, S),
\]

\[
\text{Res}_{\theta = u_{B_1}} K^{ab}(\theta) = -i f_{B_1}, \quad (a = b = B_1),
\]

where \( u_{S+S} \) and \( u_{B_1} \) are given by (22) and (23). The residues \(-i f_S\) and \(-i f_{B_1}\) are not derivable at the moment of publication.
Transverse uniform component $G_{S+S-}(q = 0, i\omega)$

Below we point out that some boundary resonances cannot be understood by any superposition of the existing resonance frequencies. This new resonance appears in $\chi''_{+-}(q = 0, \omega)$. When we are concerned with $q \approx 0$ component of correlation function $G_{S+S-}(q, i\omega)$, we may replace

$$S_x^+ \sim \frac{C_u}{2} \left[ O_S e^{-iHx} + O_S^\dagger e^{iHx} \right].$$

(43)

The fields $O_S = e^{-i(2\pi R \dot{\phi}/R)}$ and $O_S^\dagger = e^{i(2\pi R \dot{\phi}/R)}$ can create $n$ solitons, $m$ antisolitons and $l$ breathers with $n-m = 1$ and $n-m = -1$ respectively. Here $l$ can be arbitrary. Thus, minimal intermediate states in $G_{S+S-}(q = 0, i\omega)$ are a one-soliton state $|\theta_1\rangle_S$ and a one-antisoliton state $|\bar{\theta}_1\rangle_S$.

The uniform component $\chi''_{+-}(q = 0, \omega)$ does not lead to the resonance at $\omega = M_{BBS}$. This is because a “shift of the wavenumber” is accompanied with $\chi'_+- (q = 0, \omega)$. The bulk soliton resonance occurs at $\omega = E_S = \sqrt{M^2 + H^2}$, not at $\omega = M$. $E_S$ is obtained by substituting $q = \pm H$ into the Lorentz invariant dispersion relation $E(q) = \sqrt{M^2 + q^2}$ of the soliton. On the other hand, the BBS does not have $q$-dependent dispersion. Thus, the resonance $\omega = M_{BBS}$ cannot originate in $\chi''_{+-}(q = 0, \omega)$.

An interesting resonance appears in processes involving with multi-particle intermediate states. Let us consider a case in which a two-particle state $|\theta_1, \theta_2\rangle_{B+S}$ appears as an intermediate state.

$$\frac{1}{N} \frac{C_u^2}{4} \int_0^{\infty} d\tau \int_{-\infty}^{\infty} dr dX e^{i\omega \tau} \frac{1}{2} \sum_{a,b} \int_{-\infty}^{\infty} \frac{d\theta}{2\pi} \hat{K}^{ab}(\theta) \int_{-\infty}^{\infty} \frac{d\theta_1 d\theta_2}{(2\pi)^2}$$

$$= [\theta_H(x_2 - x_1) e^{-iHr} \langle \text{vac}|O_S(x_1, \tau)|\theta_1, \theta_2\rangle_{B+S} \langle \theta_2, \theta_1|O_S^\dagger(x_2, 0)| - \theta, \theta\rangle_{ab}$$

$$+ \theta_H(x_1 - x_2) e^{-iHr} \langle \text{vac}|O_S(x_2, 0)|\theta_1, \theta_2\rangle_{B+S} \langle \theta_2, \theta_1|O_S^\dagger(x_1, \tau)| - \theta, \theta\rangle_{ab}]$$

Both $B_1$ and $S$ in the intermediate state $|\theta_1, \theta_2\rangle_{B+S}$ can form the BBS. When the first breather $B_1$ forms a BBS, the resultant resonance frequency is

$$\omega = M \cosh \theta_0 + M \sin u_{SS}.$$  

Since, $M \cosh \theta_0 = \sqrt{M^2 + H^2} = E_S$ and $M \sin u_{SS} = M_{BBS}$, this resonance frequency is equal to

$$\omega = E_S + M_{BBS}.$$  

(44)

This is a simple superposition of the bulk resonance $\omega = E_S$ and the boundary resonance $\omega = M_{BBS}$. On the other hand, when the soliton $S$ forms a BBS, the resultant resonance frequency is somewhat strange, which is

$$\omega = E_1 + M_{BBS}.$$  

(45)

The first term is given by

$$E_1 = \sqrt{M_1^2 + H^2}.$$  

This resonance frequency (45) cannot be represented by any superposition of existing resonance frequencies. Since a soliton $S$ is trapped at the boundary and transformed into a BBS, a first breather $B_1$ propagates in the bulk as if it were a soliton.

INTENSITIES OF “UNKNOWN PEAKS”

In our paper, we identified the “unknown modes” found in recent experiments on KCuGaF$_6$ [5] and CuPM [6, 7] with the boundary resonances. Here we briefly comment with intensities of the “unknown peaks”. The compound KCuGaF$_6$ has larger staggered field ($c_s = 0.18$ for $H \parallel c$) than Cu-PM ($c_s = 0.083$). Thus, in Cu-PM, intensities of the staggered susceptibilities $\chi''_{+-}(q = \pi, \omega)$ and $\chi''_{zz}(q = \pi, \omega)$ are strongly suppressed because the strength of the staggered DM interaction is equal to $c_s \ll 1$ at most. We may expect that, if boundary resonances exist, they are likely to come from the uniform susceptibility $\chi''_{+-}(q = 0, \omega)$. In fact, our assignments of the “unknown modes” in Cu-PM, which are $\omega = E_{B_2}, E_{B_1} + M_1 - M_{BBS}$, are consistent with this speculation. One can find that the breather resonances $\omega = M_n$ are weaker than the “unknown mode” $U_1$ in Ref. 6. We assigned $U_1$ to $\omega = E_{B_2}$. While it looks counterintuitive that the boundary mode has the stronger absorption intensities than those of bulk modes, this relation can be understood by the weak mixing of the staggered susceptibilities in (15). The breather resonances come from the staggered part.

KCuGaF$_6$ has relatively stronger staggered field. Ref. 5 shows that the breather resonances at $\omega = M_n$
have approximately the same intensities as the soliton resonances \( \omega = E_S \). This experimental observation is also consistent with (15) and the large \( c_s \). As for the “unknown modes”, our assignments are consistent with the estimation of the large \( c_s \). We assigned “unknown modes” to \( \omega = M_{BBS}, M_1 + M_{BBS}, 2M_1 - M_{BBS}, M_2 - M_1 + M_{BBS} \), all of which originate in the transverse part \( \chi''_+(q = \pi, \omega) \).
