Abstract

We propose a label propagation approach to geolocation prediction based on Modified Adsorption, with two enhancements: (1) the removal of “celebrity” nodes to increase location homophily and boost tractability; and (2) the incorporation of text-based geolocation priors for test users. Experiments over three Twitter benchmark datasets achieve state-of-the-art results, and demonstrate the effectiveness of the enhancements.

1 Introduction

Geolocation of social media users is essential in applications ranging from rapid disaster response (Earle et al., 2010; Ashktorab et al., 2014; Morstatter et al., 2013a) and opinion analysis (Mostafa, 2013; Kirilenko and Stepchenkova, 2014), to recommender systems (Noulas et al., 2012; Schedl and Schnitzer, 2014). Social media platforms like Twitter provide support for users to declare their location manually in their text profile or automatically with GPS-based geotagging. However, the text-based profile locations are noisy and only 1–3% of tweets are geotagged (Cheng et al., 2010; Morstatter et al., 2013b), meaning that geolocation needs to be inferred from other information sources such as the tweet text and network relationships.

User geolocation is the task of inferring the primary (or “home”) location of a user from available sources of information, such as text posted by that individual, or network relationships with other individuals (Han et al., 2014). Geolocation models are usually trained on the small set of users whose location is known (e.g. through GPS-based geotagging), and other users are geolocated using the resulting model. These models broadly fall into two categories: text-based and network-based methods. Orthogonally, the geolocation task can be viewed as a regression task over real-valued geographical coordinates, or a classification task over discretised region-based locations.

Most previous research on user geolocation has focused either on text-based classification approaches (Eisenstein et al., 2010; Wing and Baldridge, 2011; Roller et al., 2012; Han et al., 2014) or, to a lesser extent, network-based regression approaches (Jurgens, 2013; Compton et al., 2014; Rahimi et al., 2015). Methods which combine the two, however, are rare.

In this paper, we present work on Twitter user geolocation using both text and network information. Our contributions are as follows: (1) we propose the use of Modified Adsorption (Talukdar and Crammer, 2009) as a baseline network-based geolocation model, and show that it outperforms previous network-based approaches (Jurgens, 2013; Rahimi et al., 2015); (2) we demonstrate that removing “celebrity” nodes (nodes with high in-degrees) from the network increases geolocation accuracy and dramatically decreases network edge size; and (3) we integrate text-based geolocation priors into Modified Adsorption, and show that our unified geolocation model outperforms both text-only and network-only approaches, and achieves state-of-the-art results over three standard datasets.

2 Related Work

A recent spike in interest on user geolocation over social media data has resulted in the development of a range of approaches to automatic geolocation prediction, based on information sources such as the text of messages, social networks, user profile data, and temporal data. Text-based methods model the geographical bias of language use in social media, and use it to geolocate non-geotagged users. Gazette expressions (Leidner and Lieberman, 2011) and geographical names (Quercini
al., 2010) were used as feature in early work, but were shown to be sparse in coverage. Han et al. (2014) used information-theoretic methods to automatically extract location-indicative words for location classification. Wing and Baldridge (2014) reported that discriminative approaches (based on hierarchical classification over adaptive grids), when optimised properly, are superior to explicit feature selection. Cha et al. (2015) showed that sparse coding can be used to effectively learn a latent representation of tweet text to use in user geolocation. Eisenstein et al. (2010) and Ahmed et al. (2013) proposed topic model-based approaches to geolocation, based on the assumption that words are generated from hidden topics and geographical regions. Similarly, Yuan et al. (2013) used graphical models to jointly learn spatio-temporal topics for users. The advantage of these generative approaches is that they are able to work with the continuous geographical space directly without any pre-discretisation, but they are algorithmically complex and don’t scale well to larger datasets. Hulden et al. (2015) used kernel-based methods to smooth linguistic features over very small grid sizes to alleviate data sparseness.

Network-based geolocation models, on the other hand, utilise the fact that social media users interact more with people who live nearby. Jurgens (2013) and Compton et al. (2014) used a Twitter reciprocal mention network, and geolocated users based on the geographical coordinates of their friends, by minimising the weighted distance of a given user to their friends. For a reciprocal mention network to be effective, however, a huge amount of Twitter data is required. Rahimi et al. (2015) showed that this assumption could be relaxed to use an undirected mention network for smaller datasets, and still attain state-of-the-art results. The greatest shortcoming of network-based models is that they completely fail to geolocate users who are not connected to geolocated components of the graph. As shown by Rahimi et al. (2015), geolocation predictions from text can be used as a backoff for disconnected users, but there has been little work that has investigated a more integrated text- and network-based approach to user geolocation.

3 Data

We evaluate our models over three pre-existing geotagged Twitter datasets: (1) GEOTEXT (Eisenstein et al., 2010), (2) TWITTER-US (Roller et al., 2012), and (3) TWITTER-WORLD (Han et al., 2012). In each dataset, users are represented by a single meta-document, generated by concatenating their tweets. The datasets are pre-partitioned into training, development and test sets, and rebuilt from the original version to include mention information. The first two datasets were constructed to contain mostly English messages.

GEOTEXT consists of tweets from 9.5K users: 1895 users are held out for each of development and test data. The primary location of each user is set to the coordinates of their first tweet.

TWITTER-US consists of 449K users, of which 10K users are held out for each of development and test data. The primary location of each user is, once again, set to the coordinates of their first tweet.

TWITTER-WORLD consists of 1.3M users, of which 10000 each are held out for development and test. Unlike the other two datasets, the primary location of users is mapped to the geographic centre of the city where the majority of their tweets were posted.

4 Methods

We use label propagation over an @-mention graph in our models. We use k-d tree discretised adaptive grids as class labels for users and learn a label distribution for each user by label propagation over the @-mention network using labelled nodes as seeds. For k-d tree discretisation, we set the number of users in each region to 50, 2400, 2400 for GEOTEXT, TWITTER-US and TWITTER-WORLD respectively, based on tuning over the development data.

Social Network: We used the @-mention information to build an undirected graph between users. In order to make the inference more tractable, we removed all nodes that were not a member of the training/test set, and connected all pairings of training/test users if there was any path between them (including paths through non-training/test users). We call this network a “collapsed network”, as illustrated in Figure 1. Note that a celebrity node with n mentions connects n(n − 1) nodes in the collapsed network. We experiment with both binary and weighted edge (based on the number of mentions connecting the given users) networks.
Baseline: Our baseline geolocation model (“MAD-B”) is formulated as label propagation over a binary collapsed network, based on Modified Adsorption (Talukdar and Crammer, 2009). It applies to a graph $G = (V, E, W)$ where $V$ is the set of nodes with $|V| = n = n_l + n_u$ (where $n_l$ nodes are labelled and $n_u$ nodes are unlabelled), $E$ is the set of edges, and $W$ is an edge weight matrix. Assume $C$ is the set of labels where $|C| = m$ is the total number of labels. $Y$ is an $n \times m$ matrix storing the training node labels, and $\hat{Y}$ is the estimated label distribution for the nodes. The goal is to estimate $\hat{Y}$ for all nodes (including training nodes) so that the following objective function is minimised:

$$C(\hat{Y}) = \sum_{i} \left[ \mu_1 (Y_i - \hat{Y}_i)^T S (Y_i - \hat{Y}_i) + \mu_2 \hat{Y}_i^T L \hat{Y}_i \right]$$

where $\mu_1$ and $\mu_2$ are hyperparameters, $L$ is the Laplacian of an undirected graph derived from $G$; and $S$ is a diagonal binary matrix indicating if a node is labelled or not. The first term of the equation forces the labelled nodes to keep their label (prior term), while the second term pulls a node’s label toward that of its neighbours (smoothness term). For the first term, the label confidence for training and test users is set to 1.0 and 0.0, respectively. Based on the development data, we set $\mu_1$ and $\mu_2$ to 1.0 and 0.1, respectively, for all the experiments. For TWITTER-US and TWITTER-WORLD, the inference was intractable for the default network, as it was too large.

There are two immediate issues with the baseline graph propagation method: (1) it doesn’t scale to large datasets with high edge counts, related to which, it tends to be biased by highly-connected nodes; and (2) it can’t predict the geolocation of test users who aren’t connected to any training user (MAD-B returns Unknown, which we rewrite with the centre of the map). We redress these two issues as follows.

Celebrity Removal To address the first issue, we target “celebrity” users, i.e. highly-mentioned Twitter users. Edges involving these users often carry little or no geolocation information (e.g. the majority of people who mention Barack Obama don’t live in Washington D.C.). Additionally, these users tend to be highly connected to other users and generate a disproportionately high number of edges in the graph, leading in large part to the baseline MAD-B not scaling over large datasets such as TWITTER-US and TWITTER-WORLD. We identify and filter out celebrity nodes simply by assuming that a celebrity is mentioned by more than $T$ users, where $T$ is tuned over development data. Based on tuning over the development
Table 1: Geolocation results over the three Twitter corpora, comparing baseline Modified Adsorption (MAD-B), with Modified Adsorption with celebrity removal (MADCEL-B and MADCEL-W, over binary and weighted networks, resp.) or celebrity removal plus text priors (MADCEL-B-LR and MADCEL-W-LR, over binary and weighted networks, resp.); the table also includes state-of-the-art results for each dataset (“—” signifies that no results were published for the given dataset; “???” signifies that no results were reported for the given metric; and “×××” signifies that results could not be generated, due to the intractability of the training data).

| Dataset                  | MAD-B | MADCEL-B | MADCEL-W | MADCEL-B-LR | MADCEL-W-LR |
|--------------------------|-------|----------|----------|-------------|-------------|
|                          | Acc@161 | Mean | Median | Acc@161 | Mean | Median | Acc@161 | Mean | Median |
| GEO TEXT                 | 50 | 683 | 146 | x x x | x x x | x x x | x x x | x x x | x x x |
| TWITTER-US               | 65 | 609 | 76 | 54 | 709 | 117 | 70 | 936 | 0 |
| TWITTER-WORLD            | 58 | 586 | 60 | 54 | 705 | 116 | 71 | 976 | 0 |
| LR (Rahimi et al., 2015) | 57 | 608 | 65 | 60 | 533 | 77 | 72 | 786 | 0 |
| LP (Rahimi et al., 2015) | 58 | 586 | 60 | 54 | 705 | 116 | 71 | 976 | 0 |
| Wing and Baldridge (2014) | 59 | 581 | 57 | 60 | 529 | 78 | 72 | 802 | 0 |

Figure 2: Effect of celebrity removal on geolocation performance and graph size. For each T performance is measured over the development set of TWITTER-US by MADCEL-W.

The label for the dongle node is based on a text-based $l_1$ regularised logistic regression model, using the method of Rahimi et al. (2015). The dongle nodes with their corresponding label confidences are added to the seed set, and are treated in the same way as other labelled nodes (i.e. the training nodes). Once again, we experiment with text-based labelled dongle nodes over both binary (“MADCEL-B-LR”) and weighted (“MADCEL-W-LR”) networks.
5 Evaluation

Following Cheng et al. (2010) and Eisenstein et al. (2010), we evaluate using the mean and median error (in km) over all test users (“Mean” and “Median”, resp.), and also accuracy within 161 km of the actual location (“Acc@161”). Note that higher numbers are better for Acc@161, but lower numbers are better for mean and median error, with a lower bound of 0 and no (theoretical) upper bound.

To generate a continuous-valued latitude/longitude coordinate for a given user from the k-d tree cell, we use the median coordinates of all training points in the predicted region.

6 Results

Table 1 shows the performance of MAD-B, MADCEL-B, MADCEL-W, MADCEL-B-LR and MADCEL-W-LR over the GEOTEXT, TWITTER-US and TWITTER-WORLD datasets. The results are also compared with prior work on network-based geolocation using label propagation (LP) (Rahimi et al., 2015), text-based classification models (Han et al., 2012; Wing and Baldridge, 2011; Wing and Baldridge, 2014; Rahimi et al., 2015; Cha et al., 2015), text-based graphical models (Ahmed et al., 2013), and network–text hybrid models (LP-LR) (Rahimi et al., 2015).

Our baseline network-based model of MAD-B outperforms the text-based models and also previous network-based models (Jurgens, 2013; Compston et al., 2014; Rahimi et al., 2015). The inference, however, is intractable for TWITTER-US and TWITTER-WORLD due to the size of the network.

Celebrity removal in MADCEL-B and MADCEL-W has a positive effect on geolocation accuracy, and results in a 47% reduction in Median over GEOTEXT. It also makes graph inference over TWITTER-US and TWITTER-WORLD tractable, and results in superior Acc@161 and Median, but slightly inferior Mean, compared to the state-of-the-art results of LR, based on text-based classification (Rahimi et al., 2015).

MADCEL-W (weighted graph) outperforms MADCEL-B (binary graph) over the smaller GEOTEXT dataset where it compensates for the sparsity of network information, but doesn’t improve the results for the two larger datasets where network information is denser.

Adding text to the network-based geolocation models in the form of MADCEL-B-LR (binary edges) and MADCEL-W-LR (weighted edges), we achieve state-of-the-art results over all three datasets. The inclusion of text-based priors has the greatest impact on Mean, resulting in an additional 26% and 23% error reduction over TWITTER-US and TWITTER-WORLD, respectively. The reason for this is that it provides a user-specific geolocation prior for (relatively) disconnected users.

7 Conclusions and Future Work

We proposed a label propagation method over adaptive grids based on collapsed @-mention networks using Modified Adsorption, and successfully supplemented the baseline algorithm by: (a) removing “celebrity” nodes (improving the results and also making inference more tractable); and (b) incorporating text-based geolocation priors into the model.

As future work, we plan to use temporal data and also look at improving the text-based geolocation model using sparse coding (Cha et al., 2015). We also plan to investigate more nuanced methods for differentiating between global and local celebrity nodes, to be able to filter out global celebrity nodes but preserve local nodes that can have high geolocation utility.
