Inference of Spatio-Temporal Functions over Graphs via Multi-Kernel Kriged Kalman Filtering

Vassilis N. Ioannidis*, Student Member, IEEE, Daniel Romero†, Member, IEEE, and Georgios B. Giannakis*, Fellow, IEEE

Abstract—Inference of space-time varying signals on graphs emerges naturally in a plethora of network science related applications. A frequently encountered challenge pertains to reconstructing such dynamic processes, given their values over a subset of vertices and time instants. The present paper develops a graph-aware kernel-based kriged Kalman filter that accounts for the spatio-temporal variations, and offers efficient online reconstruction, even for dynamically evolving network topologies. The kernel-based learning framework bypasses the need for statistical information by capitalizing on the smoothness that graph signals exhibit with respect to the underlying graph. To address the challenge of selecting the appropriate kernel, the proposed filter is combined with a multi-kernel selection module. Such a data-driven method selects a kernel attuned to the signal dynamics on-the-fly within the linear span of a pre-selected dictionary. The novel multi-kernel learning algorithm exploits the eigenstructure of Laplacian kernel matrices to reduce computational complexity. Numerical tests with synthetic and real data demonstrate the superior reconstruction performance of the novel approach relative to state-of-the-art alternatives.

Index Terms—Graph signal reconstruction, dynamic models on graphs, kriged Kalman filtering, multi-kernel learning.

I. INTRODUCTION

A number of applications involve data that admit a natural representation in terms of node attributes over social, economic, sensor, communication, and biological networks, to name a few [11], [24]. An inference task that emerges in this context is to predict or extrapolate the attributes of all nodes in the network given the attributes of a subset of them. In a finance network, where nodes correspond to stocks and edges capture dependencies among them, one may be interested in predicting the price of all stocks in the network knowing the price of some. This is of paramount importance in applications where collecting the attributes of all nodes is prohibitive, as is the case when sampling large-scale graphs, or, when the attribute of interest is of sensitive nature, such as the transmission of HIV in a social network. This task was first formulated as reconstructing a time-invariant function on a graph [24], [25].

Follow-up reconstruction approaches leverage the notions of graph bandlimitedness [5], sparsity and over-complete dictionaries [27], smoothness over the graph [12], [25], all of which can be unified as approximations of nonparametric graph functions drawn from a reproducing kernel Hilbert space (RKHS) [20]; see also [10] for semi-parametric alternatives.

In various applications however, the network connectivity and node attributes change over time. Such is the case in e.g. a finance network, where not only the stock prices change over time, but also their inter-dependencies. Hence, maximizing reconstruction performance for these time-varying signals necessitates judicious modeling of the space-time dynamics, especially when samples are scarce.

Inference of time-varying graph functions has been so far pursued mainly for slow variations [9], [14], [28]. Temporal dynamics have been modeled in [17] by assuming that the covariance of the function to be reconstructed is available. On the other hand, spatio-temporal reconstruction of generally dynamic graphs has been approached using an extended graph kernel matrix model with a block tridiagonal structure that lends itself to a computationally tractable iterative solver [18]. However, [18] neither relies on a dynamic model of the function variability, nor it provides a tractable method to learn the “best” kernel that fits the data. Furthermore, [17] and [18] do not adapt to changes in the spatio-temporal dynamics of the graph function.

The present paper fills this gap by introducing online estimators for time-varying functions on generally dynamic graphs. Specifically, the contribution is threefold.

C1. A deterministic model for time-varying graph functions is proposed, where spatial dynamics are captured by the network connectivity while temporal dynamics are described through a graph-aware state-space model.

C2. Based on this model, an algorithm termed kernel Krieger Kalman filter (KeKriKF) is developed to obtain function estimates by minimizing a kernel ridge regression (KRR) criterion in an online fashion. The proposed solver generalizes the traditional network Krieger Kalman filter (KriKF) [16], [17], [29], which relies on a probabilistic model. The novel estimator forgoes with assumptions on data distributions and stationarity, by promoting space-time smoothness through dynamic kernels on graphs.

C3. To select the most appropriate kernel, a multi-kernel (M)KriKF is developed based on the multi-kernel learning (MKL) framework. This algorithm adaptively selects the kernel that “best” fits the data dynamics within the linear span of a prespecified kernel dictionary. The structure of Laplacian kernels is exploited to reduce complexity down to the order of KeKriKF. This complexity is linear in the number of time samples, which renders KeKriKF and MKriKF appealing for online operation.

The rest of the paper is structured as follows. Sec. II contains preliminaries and states the problem. Sec. III introduces the spatio-temporal model and develops the KeKriKF. Sec. IV endows the KeKriKF with an MKL module to obtain the MKriKF. Finally, numerical experiments and conclusions are presented in Secs. V and VI, respectively.

Notation: Scalars are denoted by lowercase, column vectors by bold lowercase, and matrices by bold uppercase letters. Superscripts $^\top$ and $^\dagger$ respectively denote transpose and pseudo-inverse; $1_N$ stands for the $N \times 1$ all-one vector; $\text{diag}\{x\}$ corresponds to a diagonal matrix with the entries of $x$ on its diagonal, while $\text{diag}\{X\}$ is a vector holding the diagonal entries of $X$; and $N(\mu, \sigma^2)$ is a Gaussian distribution with mean $\mu$ and variance $\sigma^2$. Finally, if $A$ is a matrix and $x$ a vector, then $\|x\|_A^2 := x^\top A^{-1} x$ and $\|x\|_2^2 := x^\top x$.

II. PROBLEM STATEMENT AND PRELIMINARIES

Consider a time-varying graph $G_t := (V, A_t)$, $t = 1, 2, \ldots$, where $V := \{v_1, ..., v_N\}$ denotes the vertex set, and $A_t$ the $N \times N$ adjacency matrix, whose $(n, n')$-th entry $A_{n,n'}(t)$ is the nonnegative weight of the edge connecting vertices $v_n$ and $v_{n'}$ at time $t$. The edge set is $E_t := \{(v_n, v_{n'}) \in V \times V : A_{n,n'}(t) \neq 0\}$, and two vertices $v$ and $v'$ are connected at time $t$ if $(v, v') \in E_t$. The graphs $\{G_t\}_t$ in this paper are undirected and have no self-loops, which means that $A_t = A_t^\top$ and $A_{n,n}(t) = 0, \forall t, n$. The Laplacian matrix is $L_t := \text{diag}\{A_{1,N}\} - A_t$, and is positive semidefinite provided that $A_{n,n}(t) \geq 0, \forall n, n', t$; see Sec. II-A.

A time-varying graph function is a map $f : V \times T \to \mathbb{R}$, where $T := \{1, 2, \ldots\}$ is the set of time indices. Specifically, $f(v_n, t)$ represents the value of the attribute of interest at node $n$ and time $t$, e.g., the closing price of the $n$-th stock on the $t$-th day. Vector $f_t := [f(v_1, t), \ldots, f(v_N, t)]^\top \in \mathbb{R}^N$ collects the function values at time $t$.

Suppose that $S_t$ noisy observations $y(v_n, t) = f(v_n, t) + e(v_n, t), s = 1, \ldots, S_t$, are available at time $t$, where $S_t := \{n_1, \ldots, n_{S_t}\}$ contains the indices $1 \leq n_1 \leq \ldots \leq n_{S_t} \leq N$ of the sampled vertices, and $e(v_n, t)$ captures the observation error. With $y_t := [y(v_{n_1}, t), \ldots, y(v_{n_{S_t}}, t)]$ and $e_t := [e(v_{n_1}, t), \ldots, e(v_{n_{S_t}}, t)]$, the observation model in vector-matrix form is

$$y_t = S_t f_t + e_t, \quad t = 1, 2, \ldots \tag{1}$$

where $S_t \in \{0, 1\}^{S_t \times N}$ selects the sampled entries of $f_t$.

Given $y_T$, $S_T$, and $A_t$ for $t = 1, \ldots, T$, the goal of this paper is to reconstruct $f_t$ at each $t$. The estimators should operate in an online fashion, which means that the computational complexity per time slot $t$ must not grow with $t$. Observe that no statistical information is assumed available in our formulation.

A. Kernel-based reconstruction

Aiming ultimately at the time-varying $f_t$, it is instructive to outline the kernel-based reconstruction of a time-invariant $f := [f_1, \ldots, f_N]$ given $G := (V, A)$, and using samples $y = S f + e \in \mathbb{R}^S$, where $S \in \{0, 1\}^{S \times N}$ and $S < N$.

Relying on regularized least-squares (LS), we obtain

$$\hat{f} = \arg \min_f ||y - S f||_2^2 + \mu \varphi(f) \tag{2}$$

where $\mu > 0$ and the regularizer $\varphi(f)$ promotes estimates with a certain structure. For example, the so-called Laplacian regularizer $\varphi_{LR}(f) := (1/2) \sum_{n=1}^N \sum_{n'=1}^N A_{n,n'}(f_n - f_{n'})^2$ promotes smooth function estimates with similar values at vertices connected by strong links (large $A_{n,n'}$), since $\varphi_{LR}(f)$ is small when $f$ is smooth. It turns out that $\varphi_{LR}(f) = f^\top L f$; see e.g. [11, Ch. 2]. For a scalar function $r(L)$ a general graph kernel family of regularizers is obtained as $g_{KR}(f) = f^\top K f = ||f||_{K_r}^2$, where

$$K_r := L + \mu \varphi_{LR}(f)$$

or $K_r := L - \mu \varphi_{LR}(f)$.
Function \( r(\lambda) = \exp(\sigma^2 \lambda/2) \) \( \sigma^2 \geq 0 \)

| Kernel name               | Parameter | Function | Parameters |
|---------------------------|-----------|----------|------------|
| Diffusion kernel [12]     |           | \( r(\lambda) = \exp(\sigma^2 \lambda/2) \) | \( \sigma^2 \geq 0 \) |
| Band-reject               |           | \( r(\lambda) = (\alpha - \lambda)^p \) \( \alpha \geq 2, p \) |
| Bandlimited [20]          |           | \( r(\lambda_n) = \begin{cases} 1/\beta & 1 \leq n \leq B \beta > 0, B \end{cases} \) otherwise |
| Regularized Laplacian [24],[25],[30] |          | \( r(\lambda) = 1 + \sigma^2 \lambda \) | \( \sigma^2 \geq 0 \) |

TABLE I: Examples of Laplacian kernels and their associated spectral weight functions.

where \( \mu > 0 \) controls the effect of the regularizer with respect to the fitting term \( S^{-1}\|y - Sf\|_2^2 \). KRR estimators have well-documented merits and solid grounds on statistical learning theory; see e.g. [22].

So far, signal \( f \) was assumed deterministic. To present a probabilistic interpretation of KRR suppose that \( f \) is zero-mean with \( C := \mathbb{E}[ff^\top] \), and that the entries of \( e \) are uncorrelated with each other and with \( f \), and \( \sigma_e^2 := S^{-1}\mathbb{E}[\|e\|^2] \). In this setting, the KRR estimator (4) reduces to the linear minimum mean-square error (LMMSE) estimator if \( \mu S = \sigma_e^2 \) and \( K = C \). Thus, KRR generalizes LMMSE and can be interpreted as the LMMSE estimator of a random signal \( f \) with covariance matrix \( K \); see [20, Proposition 2].

III. KERNEL KRIGED KALMAN FILTER

This section presents a space-time varying model that is capable of accommodating fairly general forms of spatio-temporal dynamics. Building on this model, a novel online KRR estimator will be subsequently developed for graph functions over time-varying graphs.

A. Spatio-temporal model

An immediate approach to reconstructing \( f_t \) is to apply (4) separately per slot \( t \). This yields the instantaneous estimator (IE)

\[
\hat{f}_t^{(\nu)} := \arg \min_f \frac{1}{S_t} \|y_t - S_t f\|_2^2 + \mu \|f\|_K^2, \quad (5)
\]

where \( K_t > 0 \) is a per-slot preselected kernel matrix, and superscript \( \nu \) will be explained later. Unfortunately, such an approach does not account for the possible dynamics relating \( f_t \) to \( f_{t-1} \). However, leveraging dependencies across slots can benefit the estimator of \( f_t \) from observations \( \{y_\tau\}_{\tau \neq t} \).

To circumvent the aforementioned limitation, consider modeling the function of interest as

\[
f(v_n, t) = f^{(\nu)}(v_n, t) + f^{(\chi)}(v_n, t) \quad (6)
\]

where \( f^{(\nu)} \) captures arbitrary (even fast) temporal dynamics across sampling intervals and can be interpreted as an instantaneous component, while \( f^{(\chi)} \) represents a structured (typically slow) varying component. As an example, consider stock price prediction, where \( f^{(\nu)} \) accounts for instantaneous changes caused e.g. by political statements or company announcements at \( t \) relative to \( t - 1 \), while \( f^{(\chi)} \) captures the steady evolution of the stock market, where stock prices at slot \( t \) are closely related to prices of (possibly) other stocks at \( t - 1 \). Before delving into how these components are modeled, let \( f^{(\nu)}_t := [f^{(\nu)}(v_1, t), \ldots, f^{(\nu)}(v_N, t)]^\top \) and
\( f_t(x) := [f(x)(v_1, t), \ldots, f(x)(v_N, t)]^T \), and note that (6) can be cast into vector form as

\[
  f_t = f_t^{(\nu)} + f_t^{(x)}.  \tag{7}
\]

Vector \( f_t^{(\nu)} \) can be smooth over its entries \( (G_t) \), and captures instantaneous dependence among \( \{f(v_n, t)\}_{n=1}^N \). On the other hand, \( f_t^{(x)} \) is smooth not only over \( G_t \) but also over time, and models dependencies between \( \{f(v_n, t)\}_{n=1}^N \) and their time-lagged versions \( \{f(v_n, t-1)\}_{n=1}^N \). The smooth evolution of \( f_t^{(x)} \) over time slots adheres to the state equation

\[
  f_t^{(x)} = A_{(t,t-1)} f_{t-1}^{(x)} + \eta_t, \quad t = 1, 2, \ldots \tag{8}
\]

where \( A_{(t,t-1)} \) is a graph transition matrix, and \( \eta_t := [\eta(v_1, t), \ldots, \eta(v_N, t)]^T \in \mathbb{R}^N \) is termed state noise. Vector \( \eta_t \) will be assumed smooth over \( G_t \), meaning \( \eta(v_n, t) \) is expected to be similar to \( \eta(v_n, t) \) if \( A_{n,n'}(t) \neq 0 \). The recursion in (8) is the graph counterpart of a vector autoregressive model (VARM) of order one (see e.g., [15], [23]), and will lead to computationally efficient online KRR estimators of \( f_t \) that account for temporal dynamics [23].

Model (7) can be thought of as the graph counterpart of the model adopted in [29] to derive the kriged Kalman filter. In our context here, \( f_t^{(\nu)} \) describes small-scale spatial fluctuations within slot \( t \), whereas \( f_t^{(x)} \) captures the so-called trend across slots. Furthermore, (7) generalizes the model used in [17], where \( A_{(t,t-1)} = I_N \), for network delay prediction, where \( f_t^{(\nu)} \) represents the propagation, transmission, and processing delays and \( f_t^{(x)} \) the queuing delay at each router.

**Remark 1.** The transition matrix \( A_{(t,t-1)} \) can be interpreted as the \( N \times N \) adjacency of a generally directed “transition graph” that relates \( \{f(x)(v_n, t-1)\}_{n=1}^N \) to \( \{f(x)(v_n, t)\}_{n=1}^N \). Simplicity in estimating \( A_{(t,t-1)} \) motivates the graph version of the random walk model, where \( A_{(t,t-1)} = c I_N \) with \( c > 0 \). On the other hand, adherence to the graph, prompts the selection \( A_{(t,t-1)} = c A \), in which case (8) amounts to a diffusion process on a time-invariant \( G \).

### B. KeKriKF algorithm

This section develops an online algorithm to estimate \( f_t \), given (1) and \( \{y_t, S_t, A_t, A_{(t,t-1)}\}_{t=1}^T \) for the spatio-temporal model of \( f_t \) in (7) and (8). Unfortunately, \( \{f^{(\nu)}_t\} \) and \( \{f^{(\nu)}_t\} \) cannot be obtained by solving the system of equations comprising (1), (7), and (8) over time even if \( e_t = 0 \) and \( \eta_t = 0 \) \( \forall \tau \); simply because after replacing \( f_\tau \) with \( f^{(x)}(t) + f^{(\nu)}(t) \) \( \forall \tau \), the estimation task involves \( 2Nt \) unknowns, namely \( \{f^{(x)}_t, f^{(\nu)}_t\}_{t=1}^T \), and only \( \tilde{S} + Nt \) equations, where \( \tilde{S} := \sum_{\tau=1}^t S_\tau \) and \( \tilde{S} \leq Nt \). To obtain a solution to this underdetermined problem, one must exploit the model structure. Extending the KRR estimator in (4) to time-varying functions, suppose we wish to

\[
\minimize \quad \sum_{t=1}^T \frac{1}{S_t} \|y_t - S_\tau f^{(\nu)}_\tau - S_\tau f^{(\nu)}_\tau\|^2 \\
+ \mu_1 \sum_{t=1}^T \|f^{(x)}_\tau - A_{(\tau,\tau-1)} f^{(x)}_{\tau-1}\|^2_{K^{(x)}_\tau} + \mu_2 \sum_{t=1}^T \|f^{(\nu)}_\tau\|^2_{K^{(\nu)}_\tau},
\]

where the scalars \( \mu_1, \mu_2 \geq 0 \) control the trade-off between smoothness and data fit, while the regularizers \( \|f^{(x)}_\tau - A_{(\tau,\tau-1)} f^{(x)}_{\tau-1}\|^2_{K^{(x)}_\tau} \) and \( \|f^{(\nu)}_\tau\|^2_{K^{(\nu)}_\tau} \) affect the smoothness of \( \eta_t \) and \( f^{(\nu)}_t \) prescribed by the model. Uncorrelated (nonsmooth) perturbations \( \eta_t \) can still be captured by setting \( K^{(x)}_\tau = I_N \), which is a Laplacian kernel with \( (A_{\tau}) = 1, \forall \tau \). When available, prior information about \( \{f^{(\nu)}_\tau, \eta_t\}_{t=1}^T \) may steer the selection of suitable kernel matrices; when not available, one can resort to the algorithm in Sec. IV.

Directly solving (9) \( t \) would not lead to an online algorithm since the complexity of such an approach grows with \( t \); see Sec. II. However, we will develop next an efficient online algorithm to obtain per slot \( t \) estimates \( f^{(\nu)}_t, f^{(x)}_t \) that still account for \( \{y_t, S_t, A_t\}_{t=1}^T \).

Given \( f^{(\nu)}_t \), the first-order necessary conditions for optimality of \( f^{(\nu)}_t \) yield (cf. (9))

\[
f^{(\nu)}_t = K^{(\nu)}_t S^{T}_t (K^{(\nu)}_t + \mu_2 S_t I_{S_t})^{-1} (y_t - S_{\tau} f^{(x)}_\tau)
\]

where \( K^{(\nu)}_t := S_{\tau} K^{(\nu)} \). Notice that the overbar notation indicates \( S_t \times S_t \) matrices or \( S_t \times 1 \) vectors, and recall that without overbar their counterparts have \( N \times N \) and \( N \times 1 \), respectively. Substituting (10) into (9), we arrive at an optimization problem that does not depend on \( f^{(\nu)}_t \) for \( \tau = 1, \ldots, t \). Rewrite next the per slot \( \tau \) measurement error in (9) using (10) as

\[
\begin{align}
\frac{1}{S_t} \|y_t - S_\tau f^{(\nu)}_\tau - S_{\tau} f^{(\nu)}_\tau\|^2 & = \frac{1}{S_t} \|y_t - S_\tau f^{(\nu)}_\tau - K^{(\nu)}_\tau\| \\
& \times (K^{(\nu)} \tau + \mu_2 S_t I_{S_t})^{-1} (y_t - S_{\tau} f^{(x)}_\tau)\|2 \\
& = \frac{1}{S_t} \|[I_{S_t} - K^{(\nu)} \tau (K^{(\nu)} \tau + \mu_2 S_t I_{S_t})^{-1}] (y_t - S_{\tau} f^{(x)}_\tau)\|^2.
\end{align}
\]

The matrix inversion lemma asserts for the matrix in square brackets of (11a) that

\[
[I_{S_t} - K^{(\nu)} \tau (K^{(\nu)} \tau + \mu_2 S_t I_{S_t})^{-1}] = (I_{S_t} + \frac{1}{\mu_2 S_t} K^{(\nu)} \tau)^{-1}.
\]

\[
[I_{S_t} - K^{(\nu)} \tau (K^{(\nu)} \tau + \mu_2 S_t I_{S_t})^{-1}] = (I_{S_t} + \frac{1}{\mu_2 S_t} K^{(\nu)} \tau)^{-1}. \tag{11b}
\]
Plugging (11b) into (11a) yields

\[
\frac{1}{S_{\tau_r}}\left(\frac{1}{\mu_2} \hat{K}_r^{(\nu)} + I_{S_r}\right)^{-1}(y_{\tau_r} - S_{\tau_r}f_{\tau_r}^{(x)})
\]

\[
= (y_{\tau_r} - S_{\tau_r}f_{\tau_r}^{(x)})^T \left(\frac{1}{\mu_2} \hat{K}_r^{(\nu)} + S_{\tau_r}I_{S_r}\right)^{-T}
\times S_{\tau_r}I_{S_r} \left(\frac{1}{\mu_2} \hat{K}_r^{(\nu)} + S_{\tau_r}I_{S_r}\right)^{-1}(y_{\tau_r} - S_{\tau_r}f_{\tau_r}^{(x)}).
\]  

(11c)

Next, we express the regularizer in (9) using (10) for each \( \tau \) as

\[
\frac{1}{S_{\tau_r}}\|y_{\tau_r} - S_{\tau_r}f_{\tau_r}^{(x)}\|^2 + \mu_2\|f_{\tau_r}^{(x)}\|^2_{\hat{K}_r^{(\nu)}}
\]

\[
= \|y_{\tau_r} - S_{\tau_r}f_{\tau_r}^{(x)}\|^2_{\hat{K}_r^{(\nu)}} + \mu_2\|f_{\tau_r}^{(x)}\|^2_{\hat{K}_r^{(\nu)}}
\]  

(12)

where \( \hat{K}_r^{(\nu)} := \frac{1}{\mu_2} \hat{K}_r^{(\nu)} + S_{\tau_r}I_{S_r} \). Using (12) per slot, (9) boils down to

\[
\{\hat{f}_{\tau|\tau}^{(x)}\}_{\tau=1}^t := \arg\min_{\{f_{\tau|\tau}^{(x)}\}_{\tau=1}^t} \sum_{\tau=1}^t \|y_{\tau_r} - S_{\tau_r}f_{\tau_r}^{(x)}\|^2_{\hat{K}_r^{(\nu)}}
\]

\[
+ \mu_1 \sum_{\tau=1}^t \|f_{\tau|\tau}^{(x)} - A(t,\tau-1)f_{\tau-1|\tau-1}^{(x)}\|^2_{\hat{K}_r^{(\nu)}}
\]  

(13)

Since (13) is identical to the deterministic formulation of the Kalman filter (KF) applied to a state-space model with state noise covariance \( \hat{K}_r^{(x)} \) and measurement noise covariance \( \hat{K}_r^{(x)} \), we deduce that the KF algorithm, see e.g. [26, Ch. 17], applies readily to obtain sequentially the structured per slot \( t \) component \( \{\hat{f}_{\tau|\tau}^{(x)}\}_{\tau=1}^t \). After substituting \( \{\hat{f}_{\tau|\tau}^{(x)}\}_{\tau=1}^t \) into (10), we can find also the per slot instantaneous component \( \{\hat{f}_{\tau|\tau}^{(x)}\}_{\tau=1}^t \). The \( t \)-th iteration of our so-called KeKriKF is listed as Algorithm 1.

Summing up, we have established the following result.

**Theorem 1.** If \( \{\{\hat{f}_{\tau|\tau}^{(x)}\},\hat{f}_{\tau|\tau}^{(x)}\}_{\tau=1}^t \) solves (9) for \( t = 1, \ldots, t_1 \), the KeKriKF iterations summarized in Algorithm 1 for \( t = 1, \ldots, t_1 \) generate the subset of solutions \( \{\hat{f}_{\tau|\tau}^{(x)}\},\hat{f}_{\tau|\tau}^{(x)}\}_{\tau=1}^t \).

Clearly, the KeKriKF algorithm comprises two sub-procedures: Kalman filtering (steps S1 - S6), and kriging (step S7).

The traditional KriKF has been employed to interpolate stationary processes defined over continuous spatial domains [16], [29], and its derivation follows from a probabilistic linear-minimum mean-square error (LMMSE) criterion that relies on knowledge of second-order statistics [16], [17], [29]. Here, our KeKriKF is derived from a deterministic kernel-based learning framework, which bypasses assumptions on data distributions and stationarity and replaces knowledge of second-order (cross-)covariances with knowledge of \( K^{(\nu)} \) and \( K^{(x)} \).

Moreover, different from [7], [14], [17], [28], the novel KeKriKF can accommodate dynamic graph topologies provided \( \{K^{(\nu)}, K^{(x)}\}_{t} \) are available.

**Remark 2.** The complexity of KeKriKF is \( O(N^3) \) per slot. When the underlying graph is large \( (N \gg) \), this complexity can be managed after splitting the graph into \( N_g \) subgraphs each with at most \( \lceil N/N_g \rceil \) nodes, and employing consensus-based decentralized KF schemes along the lines of [21].

**IV. ONLINE MULTI-KERNEL LEARNING**

This section broadens the scope of the KeKriKF algorithm by employing a multi-kernel learning scheme, to bypass the need for selecting an appropriate kernel.

The performance of KRR estimators is well known to heavily depend on the choice of the kernel matrix [20]. Unfortunately, it is difficult to know which kernel matrix is most appropriate for a given problem. To address this issue, an MKL approach is presented that selects a suitable kernel matrix within the linear span of a prespecified dictionary using the available data.

In the following, consider for simplicity that \( K^{(\nu)} = K^{(x)} \), \( K^{(\nu)} = K^{(x)} \), and \( S_t = S_t \). The kernels in the dictionaries \( D^{(\nu)} := \{K^{(\nu)}[m] \in \mathbb{S}^+_1 \} \) and \( D^{(x)} := \{K^{(x)}[m] \in \mathbb{S}^+_1 \} \) will be combined to generate \( K^{(\nu)} = K^{(\nu)}(\theta^{(\nu)}) := \sum_{m=1}^{M} \theta^{(\nu)}[m] K^{(\nu)}[m] \).
and $K(\theta) = K(\theta)(\theta) := \sum_{i=1}^{N} \theta(\theta)[m]K[\theta][m]$, where $\theta(\theta) := [\theta(\theta)[1], \ldots, \theta(\theta)[N]]^T$, $\theta(\theta) := [\theta(\theta)[1], \ldots, \theta(\theta)[N]]^T$ are coefficients to be determined.

Next, consider expanding the optimization in (9) to obtain $\theta(\theta)$ along with $f_t(\theta)$, $f_t(\theta)$, as follows

$$
\minimize \frac{1}{t} \sum_{\tau=1}^{t} \left\| f_{\tau} - Sf_{\tau} - Sf_{\tau} \right\|^2
+ \rho_1 \sum_{\tau=1}^{t} \left\| f_{\tau} - A(\tau, \tau - 1) f_{\tau - 1} \right\|^2_{K(\theta)}
+ \rho_2 \sum_{\tau=1}^{t} \left\| f_{\tau} \right\|^2_{K(\theta)} + \rho_\lambda \left\| \theta(\theta) \right\|^2_2
$$

where $\rho_1, \rho_2, \rho_\lambda \geq 0$ are regularization parameters. The solution to (14) for each $t$ will be denoted as $\{\hat{f}_t(\theta), \hat{f}_t(\theta)\}_{t=1}^\tau$. Here, the data-dependent $\{\hat{f}_t(\theta), \hat{f}_t(\theta)\}$ select the kernel matrices that “best” capture the data dynamics.

Due to the presence of the weighted norms, namely $\{\left\| f_{\tau} \right\|^2_{K(\theta)} - A(\tau, \tau - 1) f_{\tau - 1} \}_{t=1}^\tau$, the problem in (14) is non-convex. Fortunately, (14) is separately convex in $\{f_{\tau}^{(\theta)}, f_{\tau}^{(\theta)}\}_{t=1}^\tau$, $\theta(\theta), \theta(\theta)$, which motivates the use of alternating minimization (AM) strategies. AM algorithms minimize the objective with respect to every block of variables, while keeping the other variables fixed [8]. Conveniently, if $\theta(\theta), \theta(\theta)$ are fixed, then (14) reduces to (9), which can be solved by Algorithm 1 for $f_{\tau}^{(\theta)}$, $f_{\tau}^{(\theta)}$ per slot $t$; see Theorem 1. Conversely, $\hat{f}_t(\theta), \hat{f}_t(\theta)$ can be obtained for fixed $\{f_{\tau}^{(\theta)}, f_{\tau}^{(\theta)}\}_{t=1}^\tau$ as specified next.

**Theorem 2.** Consider minimizing (14) with respect to $\theta(\theta)$ and $\theta(\theta)$ for fixed $f_{\tau}^{(\theta)}$ and $f_{\tau}^{(\theta)} = \hat{f}_{\tau}^{(\theta)}$, $\tau = 1, \ldots, t$, where $\{\hat{f}_{\tau}^{(\theta)}, \hat{f}_{\tau}^{(\theta)}\}_{t=1}^\tau$ are given and not necessarily the global minimizers of (14) with respect to $\{f_{\tau}^{(\theta)}, f_{\tau}^{(\theta)}\}_{t=1}^\tau$. Let $\hat{f}_{\tau}^{(\theta)} := \hat{f}_{\tau}^{(\theta)} - A(\tau, \tau - 1) \hat{f}_{\tau - 1}^{(\theta)}$, as well as $R_{\tau}^{(\theta)} := \frac{1}{\tau} \sum_{\tau=1}^{\tau} \hat{f}_{\tau}^{(\theta)} \hat{f}_{\tau}^{(\theta)}$ and $R_{\tau}^{(\theta)} := \frac{1}{\tau} \sum_{\tau=1}^{\tau} \hat{f}_{\tau}^{(\theta)} \hat{f}_{\tau}^{(\theta)}$. Then, the minimizers of (14) with respect to $\theta(\theta)$ and $\theta(\theta)$ are

$$
\hat{\theta}_t(\theta) := \arg\min_{\theta(\theta) \geq 0} \text{Tr}\{R_{\tau}^{(\theta)} K(\theta)^{-1}(\theta(\theta))\} + \frac{\rho_1}{\mu_1} \left\| \theta(\theta) \right\|^2_2
$$

(15a)

$$
\hat{\theta}_t(\theta) := \arg\min_{\theta(\theta) \geq 0} \text{Tr}\{R_{\tau}^{(\theta)} K(\theta)^{-1}(\theta(\theta))\} + \frac{\rho_2}{\mu_2} \left\| \theta(\theta) \right\|^2_2
$$

(15b)

**Proof:** To prove (15a), keep in (14) only those terms that depend on $\theta(\theta)$, and replace $\{f_{\tau}^{(\theta)}, f_{\tau}^{(\theta)}\}_{t=1}^\tau$ with $\{\hat{f}_{\tau}^{(\theta)}, \hat{f}_{\tau}^{(\theta)}\}_{t=1}^\tau$. Then, the objective in (14) reduces to $(1/t) \sum_{\tau=1}^{\tau} \hat{f}_{\tau}^{(\theta)} \hat{f}_{\tau}^{(\theta)} \left(K(\theta)^{-1}(\theta(\theta))\hat{f}_{\tau}^{(\theta)} + (\rho_1/\mu_1) \left\| \theta(\theta) \right\|^2_2\right)$. Next, using the linearity and cyclic invariance of the trace it follows that

$$
\text{Tr}\{R_{\tau}^{(\theta)} K(\theta)^{-1}(\theta(\theta))\hat{f}_{\tau}^{(\theta)}\} = \text{Tr}\{R_{\tau}^{(\theta)} K(\theta)^{-1}(\theta(\theta))\} = \text{Tr}\{R_{\tau}^{(\theta)} K(\theta)^{-1}(\theta(\theta))\},
$$

which proves (15a). The proof of (15b) follows along the same lines.

Thus, Theorem 2 simplifies the objective that has to be minimized to find $\hat{\theta}_t(\theta)$ and $\hat{\theta}_t(\theta)$. With $K(\theta) = \sum_{m=1}^{M} \theta(m)K[m]$, problems (15a) and (15b) are of the form

$$
\hat{\theta} := \arg\min_{\theta \geq 0} \text{Tr}\{KK^{-1}(\theta)\} + \rho\left\| \theta \right\|^2_2
$$

(16)

for some $R \in \mathbb{R}^{N \times N}$, $\rho \geq 0$, and $D = \{K[m]\}_{m=1}^{N}$. Due to their resemblance to covariance matching [19], problem (16), and hence (15a) and (15b) will be referred to as kernel matching.

Theorem 2 suggests an online AM procedure to approximate the solution to (14), where Algorithm 1 and a solver for (16) termed online kernel matching (OKM) are executed alternatingly. This is summarized as Algorithm 2, and it is termed multi-kernel KriKF (MKriKF). Algorithm 2 does not generally find a global optimum of (14); yet, finding such an optimum may not be critical in practice, since it cannot be computed in polynomial time.

The rest of this section develops the OKM algorithm for solving (16) when $D$ comprises Laplacian kernels. The first step is to exploit the fact that all Laplacian kernel matrices associated with a given graph have common eigenvectors.

**Proposition 1.** Consider the eigenvalue decompositions $\{K[m] = U \text{diag}(\Lambda[m])U^T\}_{m=1}^{N}$ and let $T := U^TRU$. Upon defining $\Lambda(\theta) := \text{diag}\{\sum_{m=1}^{N} \theta(m)\Lambda[m]\}$ and $\phi(\theta) := \text{Tr}\{(T \Lambda^{-1}(\theta)) + \rho\left\| \theta \right\|^2_2\}$, (16) can be equivalently written as

$$
\hat{\theta} := \arg\min_{\theta \geq 0} \phi(\theta)
$$

(17)

**Proof:** Since $K(\theta) = \sum_{m=1}^{N} \theta(m)U \text{diag}(\Lambda[m])U^T = U \Lambda(\theta)U^T$, (17) follows by noting that

$$
\text{Tr}\{KK^{-1}(\theta)\} = \text{Tr}\{UU^T \Lambda^{-1}(\theta)U^T\} = \text{Tr}\{U^T \Lambda^{-1}(\theta)\} = \text{Tr}\{T \Lambda^{-1}(\theta)\}.
$$

□
Proposition 1 establishes that (16) can be expressed as (17) when the kernels in \( D \) share eigenvectors, as is the case of Laplacian kernels; cf. Sec. II-A.

Proposition 2. When \( \theta \geq 0 \), function \( \phi(\theta) \) is strongly convex and differentiable with gradient

\[
\nabla \phi(\theta) = v(\theta) + 2\rho \theta
\]

where \( v(\theta) := -[\text{Tr}\{\text{diag}\{\hat{\lambda}[1]\}T\}, \ldots, \text{Tr}\{\text{diag}\{\hat{\lambda}[M]\}T\}] \), with \( \hat{\lambda}[m] := [\hat{\lambda}_1[m], \ldots, \hat{\lambda}_N[m]]^\top \) and \( \hat{\lambda}_n[m] := \lambda_n[m]/\sum_{m=1}^{M} \theta[m] \lambda_n[m] \).

Proof: Because \( T \) is a positive semidefinite matrix and \( \lambda[m] \geq 0 \) \( \forall m \), it can be easily seen that \( \text{Tr}\{T \Lambda^{-1}(\theta)\} \) is convex over \( \theta \geq 0 \). And since \( \rho\|\theta\|_2^2 \) is strongly convex, it follows by its definition that \( \phi(\theta) \) is strongly convex. To obtain the gradient observe that

\[
\frac{\partial \phi}{\partial \theta[m]} = -\text{Tr}\{\Lambda^{-1}(\theta) \text{diag}\{\lambda[m]\} \Lambda^{-1}(\theta)T\} + 2\rho \theta[m]
\]

and \( \Lambda^{-1}(\theta) \text{diag}\{\lambda[m]\} \Lambda^{-1}(\theta) = \text{diag}\{\hat{\lambda}[m]\} \).

As (17) entails a strongly convex and differentiable objective, and projections on its feasible set are easy to obtain, we are motivate to solve (17) through projected gradient descent (PGD) [6]. Besides its simplicity, PGD converges linearly to the global minimum of (17). The general PGD iteration is

\[
\theta^{k+1} = [\theta^k - s^k \nabla \phi(\theta^k)]^+, \quad k = 0, 1, \ldots
\]

where \( s^k \) is the stepsize chosen e.g. by the Armijo rule [6], \( \theta^0 \) is a feasible initial step, and \([\cdot]^+\) denotes projection on the non-negative orthant \{\( \theta[m] \geq 0, \, m = 1, \ldots, M \}\}. The overall algorithm is termed OKM, and it is listed as Algorithm 3.

Observe that \( \theta^0 \) in Algorithm 3 is initialized with the output of Algorithm 3 in the previous iterate, namely \( \hat{\theta}_{t-1} \). This is a warm start that considerably speeds up convergence of Algorithm 3 since \( \phi(\theta) \) is expected to change slowly across the iterations in Algorithm 2. An interesting byproduct of the OKM algorithm is its ability to adapt to changes in the spatio-temporal dynamics of the graph functions by adjusting the coefficients \{\( \hat{\theta}^{(\nu)}_t, \hat{\theta}^{(\chi)}_t \)\}, and consequently the kernel matrices.

In view of Proposition 2, finding each entry of \( \nabla \phi(\theta) \) in Algorithm 3 requires \( O(N) \) operations. Computing the gradient through (18) exploits the common eigenvectors of \{\( K[m] \)\}_{m=1}^{M} and avoids the inversion of the \( N \times N \) matrix \( K(\theta) \) that is required when calculating the gradient for the general formulation (16), where \{\( K[m] \)\}_{m=1}^{M} need not share eigenvectors. The complexity of evaluating the gradient is therefore reduced from a prohibitive \( O(N^3 M) \) for general kernels to an affordable \( O(NM) \) for Laplacian kernels, which amounts to considerable computational savings especially for large-scale networks. With \( K \) denoting the number of PGD iterations for convergence, the overall computational complexity of OKM is therefore \( O(NMK) \). Typically, \( N^3 \geq NMK \) and hence the complexity of Algorithm 2 is \( O(N^3) \), with learning the appropriate linear combination of kernels through MKL does not increase the complexity order that can be further reduced as suggested in Remark 2.

Remark 3. The algorithms in this section adopted a fixed kernel dictionary over time, namely \( D = \{K[m] \in \mathbb{S}_+^N\}_{m=1}^{M} \). If the topology changes over time, the Laplacian kernel matrices change as well, cf. (3). To ac-

### Algorithm 2: Multi-kernel KriKF (MKriKF)

**Input:** \( D^{(\nu)}; D^{(\chi)}; L = U^\top \text{diag}\{\lambda\} U \);

1. Initialize: \( \hat{\theta}^0 = \hat{\theta}(x) = [1, 0, \ldots, 0] \), \( \hat{f}(x) = 0 \), \( \theta^0 = \hat{\theta}(x) \), \( \lambda^{(\nu)}_0 = \frac{1}{\mu} K^{(\nu)}[1] \), \( \lambda^{(\chi)}_0 = \text{diag}\{U K^{(\nu)}[m] U^\top\} \forall m \), \( \hat{\lambda}^{(\nu)}_0[m] = \text{diag}\{U K^{(\nu)}[m] U^\top\} \forall m \).

2. for \( t = 1, 2, \ldots \) do

3. Input: \( A_{(t,t-1)} \in \mathbb{R}^{N \times N}; y_t \in \mathbb{R}^{S_t}; S_t \in \{0, 1\}^{S_t \times N} \).

4. \( K^{(\nu)}_t = K^{(\nu)}(\hat{\theta}^{(\nu)}_t) \)

5. \( K^{(\chi)}_t = K^{(\chi)}(\hat{\theta}^{(\chi)}_t) \)

6. \( \{\hat{f}^{(\nu)}_t, \hat{f}^{(\chi)}_t\} = \text{KeKriKF}(K^{(\nu)}_{t-1}, K^{(\chi)}_{t-1}, A_{(t,t-1)} \)

7. Update \( R^{(\nu)}_t \) and \( R^{(\chi)}_t \).

8. \( T^{(\nu)}_t = U^\top R^{(\nu)}_t U \)

9. \( T^{(\chi)}_t = U^\top R^{(\chi)}_t U \)

10. \( \hat{\theta}^{(\nu)}_t = \text{OKM}(\lambda^{(\nu)}_t, T^{(\nu)}_t, \hat{\theta}^{(\nu)}_{t-1}) \)

11. \( \hat{\theta}^{(\chi)}_t = \text{OKM}(\lambda^{(\chi)}_t, T^{(\chi)}_t, \hat{\theta}^{(\chi)}_{t-1}) \)

12. Output: \( \hat{f}^{(\nu)}_t, \hat{f}^{(\chi)}_t; M_t \).

13. end for

### Algorithm 3: Online kernel matching (OKM)

**Input:** \( \{\lambda[m]\}_{m=1}^{M} \); \( T_t \in \mathbb{S}_+^N \); \( \hat{\theta}_{t-1} \in \mathbb{R}_+^M \).\n
1. Initialize: \( \theta^0 = \hat{\theta}_{t-1} \).

2. while stopping criterion not met do

3. \( \theta^{k+1} = [\theta^k - s^k \nabla \phi(\theta^k)]^+ \)

4. \( k \leftarrow k + 1 \)

5. end while

**Output:** \( \theta^k \).
commodate this scenario, one can restart Algorithm 2 whenever the topology changes, say at time \( t_c \), and initialize \( \tilde{f}_{0,t}^{(x)} \leftarrow f_{0,t}^{(x)} \), \( M_{0,t} \leftarrow M_{t,t} \), as well as replace the Laplacian kernels in \( \mathcal{D} \) with the ones corresponding to the new topology.

**Remark 4.** To accommodate a certain degree of non-stationarity one may consider using the following matrices

\[
\tilde{R}_t^{(\nu)} = \sum_{\tau=1}^{t} \gamma_{\nu} t^{-\tau} f_{\nu}^{(\nu)} f_{\nu}^{(\nu)^T} + \gamma_{\nu}^2 I \tag{21a}
\]

\[
\tilde{R}_t^{(x)} = \sum_{\tau=1}^{t} \gamma_{x} t^{-\tau} f_{\tau}^{(x)} f_{\tau}^{(x)^T} + \gamma_{x}^2 I \tag{21b}
\]

instead of \( \tilde{R}_t^{(\nu)} \) and \( \tilde{R}_t^{(x)} \), where \( \gamma_{\nu}, \gamma_{x} \in (0,1) \) are forgetting factors that weigh exponentially past observations, and ensure invertibility of matrices \( \tilde{R}_t^{(\nu)} \) and \( \tilde{R}_t^{(x)} \). Moreover, \( \tilde{R}_t^{(\nu)} \) and \( \tilde{R}_t^{(x)} \) can be updated recursively as

\[
\tilde{R}_t^{(\nu)} = \gamma_{\nu} \tilde{R}_{t-1}^{(\nu)} + \tilde{f}_{t}^{(\nu)} \tilde{f}_{t}^{(\nu)^T} \tag{22a}
\]

\[
\tilde{R}_t^{(x)} = \gamma_{x} \tilde{R}_{t-1}^{(x)} + \tilde{f}_{t}^{(x)} \tilde{f}_{t}^{(x)^T} \tag{22b}
\]

which significantly reduces the required memory for the computation with respect to (21), since \( \{ \tilde{f}_{\tau}^{(\nu)}, \tilde{f}_{\tau}^{(x)} \}_{\tau=1}^{t} \) need not be stored.

**V. SIMULATIONS**

This section evaluates the performance of the developed algorithms by means of numerical tests with synthetic and real data. The proposed algorithms are compared with: (i) The least mean-square (LMS) algorithm in [14] with step size \( \mu_{\text{LMS}} \); and (ii) the distributed least-squares reconstruction (DLSR) algorithm in [28] with step sizes \( \mu_{\text{DLSR}} \) and \( \beta_{\text{DLSR}} \). Both LMS and DLSR can track slowly time-varying \( B \)-bandlimited graph signals.

The performance of the aforementioned approaches is quantified through the normalized mean-square error (NMSE)

\[
\text{NMSE} := \frac{\mathbb{E}\left[ \sum_{\tau=1}^{t} \left| \left| S_{\tau}^{c} (f_\tau - \tilde{f}_{\tau|\tau}) \right| \right|^2 \right]}{\mathbb{E}\left[ \sum_{\tau=1}^{t} \left| \left| S_{\tau}^{c} f_\tau \right| \right|^2 \right]}
\]

where the expectation is taken over the sample locations, and \( S_{\tau}^{c} \) is an \( (N-S_{\tau}) \times N \) matrix comprising the rows of \( I_N \) whose indices are not in \( S_{\tau} \). For all tests, \( S_{\tau} \) is chosen uniformly at random without replacement over \( \mathcal{V} \) and kept constant over time; that is, \( S_{\tau} = S_{\tau+1} \), \( \forall \tau \). The parameters of different algorithms were selected using cross-validation to minimize their NMSE. Notice that our MKriKF, which learns the kernel that “best” fits the data, requires minimal parameter tuning.

### A. Numerical tests on synthetic data

To construct a graph, consider the dataset in [4], which contains timestamped messages among students at the University of California, Irvine, exchanged over a social network during 90 days. The sampling interval \( t \) is one day. A graph is constructed such that the edge weight \( A_{n,n'}(t) \) counts the number of messages exchanged between student \( n \) and \( n' \) in the \( k \)-th month, where \( k = 1, 2, 3 \) and \( 30(k-1) + 1 \leq t \leq 30k \). Hence, \( A_t \) changes across months. A subset of \( N = 310 \) users for which \( A_t \) corresponds to a connected graph \( \forall t \) is selected. At each \( t \), \( f_t \) was generated by superimposing a \( B \)-bandlimited graph function with \( B = 5 \) and a spatiotemporally correlated signal. Specifically, \( f_t = f_t^{(\nu)} + f_t^{(x)} = \sum_{\nu=1}^{5} \gamma_{\nu} \tilde{u}_{\nu} + f_t^{(\nu)} \), where \( \gamma_{\nu} \sim N(0,1) \) for all \( t \), while \( \{ \tilde{u}_{\nu} \}_{\nu=1}^{5} \) denote the eigenvectors associated with the 5 smallest eigenvalues of \( L_t \), and \( f_t^{(\nu)} \) is generated according to (8) with \( A(t,t-1) = 0.03(A_{t-1} + I_N) \), \( \eta \sim N(0, C_{\eta}) \), and \( C_{\eta} \) is a diffusion kernel with \( \sigma = 0.5 \). Function \( f(v_n, t) \) is therefore smooth with respect to the graph and can be interpreted e.g. as the time that the \( n \)-th student spends on the specific social network during the \( t \)-th day.

The first experiment justifies the proposed decomposition by assessing the impact of dropping either \( f_t^{(\nu)} \) or \( f_t^{(x)} \) from the right hand side of (7). The KriKF algorithm uses diffusion kernels \( K_t^{(\nu)} \) and \( K_t^{(x)} \) with parameters \( \sigma = 1.5 \) and \( \sigma = 0.5 \), respectively. Fig. 2 depicts the NMSE with \( S = 217 \) for the KeKriKF; the Kalman filter (KF) estimator, which results from setting \( f_t^{(\nu)} = 0 \) for all \( t \) in the KeKriKF; as well as kernel Kriging (KKr), which the KeKriKF reduces to if \( f_t^{(x)} = 0 \) for all \( t \). As observed, KeKriKF, which accounts for both summands in (7), outperforms those algorithms that account for only one of them. Moreover, the low NMSE of KeKriKF in reconstructing the \( N - S = 310 - 217 = 93 \) unavailable node values reveals that this algorithm is capable of efficiently capturing the spatial as well as the temporal dynamics over time-varying topologies.

Next, the robustness of KriKriKF is evaluated when the connectivity of \( G_t \), captured by \( A_t \), exhibits abrupt changes over \( t \). Synthetic time-varying networks of size \( N = 81 \) were generated using the Kronecker product model, which effectively captures properties of real graphs [13]. The prescribed “seed matrix”

\[
D_0 := \begin{bmatrix}
1 & 0.1 & 0.7
0.3 & 0.1 & 0.5
0 & 1 & 0.1
\end{bmatrix}
\]
produces the $N \times N$ matrix $D := D_0 \otimes D_0 \otimes D_0 \otimes D_0$, where $\otimes$ denotes the Kronecker product. An initial adjacency matrix $A_0$ was constructed with entries $A_{n,n'}(0) \forall n$, $A_{n,n'}(0) \sim \text{Bernoulli}(D_{n,n'})$ for $n > n'$, and $A_{n,n'}(0) = A_{n',n}(0)$ for $n < n'$. Next, the following time-varying graph model was generated: at each $t_c = 10\kappa$, $\kappa = 1, 2, \ldots$, each entry of $A_t$ changes with probability $p_{n,n'} = \sum_k A_{n,k}(t_c) \frac{\sum_l A_{l,n'}(t_c)}{\sum_k \sum_l A_{k,l}(t_c)}$ as $A_{n,n'}(t_c + 1) = A_{n,n'}(t_c) + |\xi_{n,n'}(t_c)|$ for $n > n'$ where $\xi_{n,n'}(t_c) \sim \mathcal{N}(0, \sigma_A)$ and $A_{n,n'}(t_c + 1) = A_{n,n'}(t_c + 1)$ for $n < n'$. This choice of $p_{n,n'}$ is based on the “rich get richer” attribute of real networks, where new connections are formed between nodes with high degree [13]. Moreover, the edge $(v_n, v_{n'})$ is deleted at each $t_d = 20\kappa$, $\kappa = 1, 2, \ldots$ with probability 0.1; that is, $A_{n,n'}(t_d + 1) = A_{n,n'}(t_d + 1) = 0$, as long as the graph remains connected. By varying $\sigma_A$, we obtain different time-varying graphs. A graph function was generated for each time-varying graph as follows

$$f_t = \delta A_t f_{t-1} + \sum_{i=1}^{10} \gamma^{(i)}(t) u^{(i)}_t$$  \hspace{1cm} (23)

where $\delta = 10^{-2}$ is a forgetting factor, $\sum_{i=1}^{10} \gamma^{(i)}(t) u^{(i)}_t$ is a graph-bandlimited component with $\gamma^{(i)}(t) \sim \mathcal{N}(0, 1)$, and $\{u^{(i)}_t\}_{i=1}^{10}$ are the eigenvectors associated with the 10 smallest eigenvalues of $L_t$. Algorithm 1 employs a bandlimited kernel with $\beta = 10^3$ and $B$ for $K_t^{(\nu)}$, a diffusion kernel with $\sigma = 0.5$ for $K_t^{(\chi)}$, and $A_{t,t-1} = 10^{-3}(A_{t-1} + I_N)$. Fig. 3 plots the NMSE of the KeKriKF algorithm as a function of $\sigma_A$, which determines how rapidly the graph changes. As observed, the KeKriKF algorithm can effectively cope with different degrees of time variation.

### B. Temperature prediction

Consider the dataset [1] provided by the National Climatic Data Center, which comprises hourly temperature measurements at $N = 109$ measuring stations across the continental United States in 2010. A time-invariant graph was constructed as in [18], based on geographical distances. The value $f(v_n, t)$ represents the $t$-th temperature sample recorded at the $n$-th station. The sampling interval is one hour for the first experiment, and one day for the second. KeKriKF employs diffusion kernels with parameter $\sigma = 1.8$ for $K_t^{(\nu)}$, $K_t^{(\chi)} = 10^{-5}I_N$, and a transition matrix $A_{t,t-1} = 5 \cdot 10^{-4}(A_{t-1} + I_N)$. MKriKF is configured as follows: $D^{(\nu)}$ contains $M_{\nu} = 40$ diffusion kernels with parameters $\{\sigma[m]\}_{m=1}^{40}$, with $\sigma[m] \sim \mathcal{N}(2, 0.5), \forall m$; $D^{(\chi)}$ contains 44 diffusion kernels with parameters $\{\sigma[m]\}_{m=1}^{44}$, where $\sigma[m] \sim \mathcal{N}(1, 0.2), \forall m$, and an identity kernel $K^{(\chi)} = I_N$.

Fig. 4 depicts the true temperature along with its estimates for a station $n$ that is not sampled, meaning $n \notin S$, with $S = 44$. Clearly, KeKriKF accurately tracks the temperature by exploiting spatial and temporal dynamics, but MKriKF outperforms KeKriKF by learning those dynamics from the data. The random sampling set selection heavily affects performance of the LMS algorithm; for adaptive selection of $S$ see [14].

Fig. 5 compares the NMSE of all considered approaches for $S = 44$. Observe the superior performance of the proposed reconstruction methods, which in this scenario exhibit roughly the same NMSE.

### C. GDP prediction

The next dataset is provided by the World Bank Group [2], and comprises gross domestic product (GDP)
per capita for \( N = 127 \) countries for the years 1960-2016. A time-invariant graph was constructed using the correlation between the GDP of different countries for the first 25 years. The graph function \( f(v_n, t) \) denotes the GDP reported at the \( n \)-th country and \( t \)-th year for \( t = 1985, \ldots, 2016 \). The graph Fourier transform of the GDP in the first 25 years is defined as \( \hat{f}_n := u_n^T \mathfrak{f} \) \( \forall n \), where \( u_n \) denotes the \( n \)-th eigenvector of the Laplacian matrix; see [24], shows that the graph frequencies \( \hat{f}_k \) take small values for \( 4 < k < 123 \), and large values otherwise. Motivated by the aforementioned observation, the KeKriKF is configured with a band-reject kernel \( K^{(\nu)} \) with \( k = 6, l = 6, \beta = 15 \); see Table I, \( K^{(\chi)} = 10^{-3} I_N \), and \( A_{(t,t-1)} = 10^{-5}(A_{t-1} + I_N) \). MKriKF adopts a \( D^{(\nu)} \) with \( M_\nu = 16 \) band-reject kernels with \( k \in [2, 5], l \in [1, 4], \beta = 15 \), and a \( D^{(\chi)} \) with 60 diffusion kernels with parameters \( \{\sigma[m]\}_{m=1}^{60} \), where \( \sigma[m] \sim \mathcal{N}(2, 0.5) \) \( \forall m \), and an identity kernel \( K^{(\chi)}[61] = I_N \).

Fig. 6 depicts the actual GDP as well as its estimates for Greece, which is not contained in the sampled countries. Clearly, both MKriKF and KeKriKF, track the GDP evolution over the years with greater accuracy than the considered alternatives. This is expected because the graph function does not adhere to the graph bandlimited model assumed by DLSR and LMS.

Fig. 7 reports NMSE over time, where the proposed algorithms achieve the smallest NMSE. The data-driven MKriKF outperforms KeKriKF, which is configured manually.
D. Network delay prediction

The last dataset records measurements of path delays on the Internet2 backbone [3]. The network comprises 9 end-nodes and 26 directed links. The delays are available for \( N = 70 \) paths at every minute. The paths connect origin-destination nodes by a series of links described by the path-link routing matrix \( \Pi \in \{0, 1\}^{N \times 26} \), whose \((n, l)\) entry is \( \Pi_{n,l} = 1 \) if path \( n' \) traverses link \( l \), and 0 otherwise. A graph is constructed with each vertex corresponding to one of these paths, and with the time-invariant adjacency matrix \( A \in \mathbb{R}^{N \times N} \) given by

\[
A_{n,n'} = \frac{\sum_{l=1}^{26} \Pi_{n,l} \Pi_{n',l}}{\sum_{l=1}^{26} \Pi_{n,l} + \sum_{l=1}^{26} \Pi_{n',l} - \sum_{l=1}^{26} \Pi_{n,l} \Pi_{n',l}}
\]

(24)

for \( n, n' = 1, \ldots, N \), \( n \neq n' \). Expression (24) was selected to assign a greater weight to edges connecting vertices whose associated paths share a large number of links. This is intuitively reasonable since paths with common links usually experience similar delays [7]. Function \( f(v_n, t) \) denotes the delay in milliseconds measured at the \( n \)-th path and \( t \)-th minute. The KeKriKF algorithm employs a diffusion kernel with parameter \( \sigma = 2.5 \) for \( K_t^{(\nu)} \), \( K_t^{(\chi)} = 0.002I_N \), and \( A_{(t,t-1)} = 0.005(A_{t-1} + I_N) \). The MKriKF is configured as follows: \( D^{(\nu)} \) contains \( M_\nu = 40 \) diffusion kernels with parameters \( \{\sigma[m] \}_{m=1}^{40} \) with \( \sigma[m] \sim \mathcal{N}(4, 0.5), \forall m \); \( D^{(\chi)} \) contains 60 diffusion kernels with parameters \( \{\sigma[m] \}_{m=1}^{60} \) with \( \sigma[m] \sim \mathcal{N}(1, 0.1), \forall m \), and an identity kernel \( K^{(\chi)} |_{61} = I_N \).

Fig. 8 depicts the NMSE when \( S = 20 \). KeKriKF and MKriKF are seen to outperform competing methods.

Finally, the proposed MKriKF will be evaluated in tracking the delay over the network from \( S = 56 \) randomly sampled path delays. To that end, delay maps are traditionally employed, which depict the network delay per path over time and enable operators to perform troubleshooting; see also [17]. The paths for the delay maps in Fig. 9 are sorted in increasing order of the true delay at \( t = 1 \). Clearly, the delay map recovered by MKriKF in Fig. 9b visually resembles the true delay map in Fig. 9a.

VI. Conclusions

This paper introduced online estimators to reconstruct dynamic functions over (possibly dynamic) graphs. In this context, the function to be estimated was decomposed in two parts: one capturing the spatial dynamics, and the other jointly modeling spatio-temporal dynamics by means of a state-space model. A novel kernel kriged Kalman filter was developed using a deterministic RKHS approach. To accommodate scenarios with limited prior information, an online multi-kernel learning technique was also developed to allow tracking of the spatio-temporal dynamics of the graph function. The structure of Laplacian kernels was exploited to achieve low computational complexity. Through numerical tests with synthetic as well as real-data, the novel algorithms were observed to perform markedly better than existing alternatives. Future work includes distributed implemen-
tations of the proposed filtering algorithms, and data-driven learning of $A(t,t-1)$.
