Abstract

The objective of this study was to evaluate the effect of universal adhesives application time to enamel through shear bond strength (SBS), adhesive remnant index (ARI), and morphological enamel integrity. Bovine incisors were divided into four groups according to bonding system protocol (n=20): (1) conventional etch-and-rise adhesive – Transbond XT Primer (P-XT); (2) one-step self-etching adhesive – Transbond Self Etching Primer (T-SEP); (3) one universal adhesive – Single Bond Universal, which were rubbed for 20s (SBU-20) or 40s (SBU-40). Transbond XT composite was used to bond the brackets to enamel. SBS was evaluated in a universal test machine at 0.5mm/minute. ARI was determined under x12.5 magnification and enamel damage was evaluated through scanning electron microscope (SEM) after debonding (n=10). SBS data were compared using one-way ANOVA and Tukey’s test. The Kruskal–Wallis test was used to compare the ARI scores (α =0.05). The P-XT and T-SEP groups showed significantly higher bond strength than SBU-20 and SBU-40 (p<0.05). The ARI was similar for all groups (p>0.05). SEM showed enamel damage only in T-SEP and P-XT groups. Conventional ‘etch and rinse’ and ‘self-etch’ adhesives had the highest shear bond strength, but they were associated with more enamel damage compared to universal adhesives. The application of universal adhesives with the time recommended by the manufacturer — ensure satisfactory bond strength and enamel integrity.

Keywords: Orthodontic brackets; Dental bonding; Orthodontics.
1. Introduction

It is essential that dental adhesives used to bond orthodontic brackets to enamel provide enough bond strength between them to prevent spontaneous dislodgements during treatment. Adhesives should also not induce damage to the enamel surface when removed (Lamper et al., 2014). The displacement of brackets during orthodontic treatment can occur due to an unsatisfactory bonding with dental structure, increasing treatment time and costs (Almosa & Zafar, 2018). Occasionally, excessive forces on removing the orthodontic brackets may cause enamel damage (Meeran, 2013), as in, it is recommended that resin materials used on brackets bonding should stay adhered to the teeth surface after its intentional removal4.

Values of 6 MPa and 8 MPa have been reported to be suitable to tolerate masticatory forces as well as to preserve dental structure during brackets’ removal (Alshahrani et al., 2018). Bond strength values higher than 12 MPa revealed a 70% increase in the risk of enamel damage (Lamper et al., 2014), which is the case when using phosphoric acid 37% (Ibrahim et al., 2020). Self-etching adhesives for specific use in orthodontics were developed to reduce the enamel damage, the complexity of bonding technique and to improve clinical time (Bayar & Çokakoğlu et al., 2020). However, these adhesives need a low pH value to achieve enamel etching and retention patterns similar to those obtained with the established adhesive - acid etching systems. Thus, similar patterns of enamel damage have also been reported (Lamper et al., 2014).

A group of versatile adhesives, called “universal adhesives”, can be applied in both conventional and self-etching techniques (Perdigão & Swift, 2015). It is possible due to the distinguished composition of these products — based on the presence of MDP monomer, which is able to chemically adhere to different substrates. The ability of chemical bonding of MDP to hydroxyapatite promotes a long-lasting interaction (Carrilho et al., 2019) that may provide enough retention of brackets until the end of the treatment, and protection of the dental enamel structure.

Universal adhesives used without previous application of phosphoric acid, has shown to be less efficient on the bond strength to enamel compared to conventional adhesives and strong self-etching agents (Loguercio et al., 2015). Thus, an
increase in the universal adhesives’ application time has been recommended to enhance the bond strength to dental structure (Loguercio et al., 2015); however, it is not known so far if it may cause enamel damage.

Thus, the aim of this in vitro study was to evaluate the effect of universal adhesives application time on shear bond strength (SBS), adhesive remnant index (ARI), and enamel integrity of orthodontic brackets bonded to bovine enamel. The null hypotheses were: (1) there is no difference between shear bond strength (SBS) of the different adhesive protocols studied and; (2) the adhesive remnant index (ARI) distribution has no differences between the studied groups.

2. Methodology

Specimen preparation

This study was submitted to the Animal Ethics Committee (CEUA/UFES/0017-2017). Eighty newly extracted bovine teeth were used, which were stored for a maximum of 2 weeks in a 0.5% chloramine-T solution, at 4°C in a fridge. The criteria for tooth selection included intact enamel, no cracks, no gross damage (10x magnification) and no caries.

The teeth were cleaned and polished with pumice and rubber prophylactic cups for 30 seconds, and embedded on a PVC ring (Tigre, Joinville, SC, Brazil) filled with Durone type IV gypsum (Dentsply, York, Pennsylvania, USA), exhibiting the crown on the top of the cylinder. The bonding area (14.31 mm²) was delimited with an adhesive paper (Velasquez et al., 2006).

The specimens were randomly separated and numbered into four groups of twenty specimens each. The enamel surfaces were carefully dried with oil-free compressed air at a distance of 10 mm for 5 s. Table 1 lists the bonding protocol used for each group. The resin composite Transbond XT (3M Unitek, Seefeld, Germany) was applied on the mesh-base of metal brackets (Edgewise bracket for tooth 21; bonding area: 14.31 mm²; Morelli Orthodontia, Sorocaba, SP Brazil) that were pressed on teeth with a force of 200gf using a tensiometer (Morelli Orthodontia, Sorocaba, SP Brazil). The excess of resin composite was carefully removed and light-cured using a light emitting diode (LED Bluephase (Ivoclar Vivadent, Schaan, SWZ) with 1,200 mW/cm² irradiance and one exposure of 20 seconds in each side of the bracket (mesial and distal), for a total exposure time of 40 s. The specimens were immersed in distilled water for 24 h at 37 °C until shear bond strength test. A single operator was responsible to perform all bonding procedures.

**Table 1. Description of the studied groups.**

| Group   | Type of adhesive          | Manufacturer          | Application protocol                                             |
|---------|---------------------------|-----------------------|------------------------------------------------------------------|
| P-XT    | 2-step Transbond XT       | 3M/ESPE, St.          | Etch enamel with 37% phosphoric acid gel for 15 s; Rinse thoroughly for 30 s; Apply one layer Light cure for 20 s |
| (Control Group) | Primer XT (P-XT) | Paul, MN, EUA       | of Transbond XT adhesive; Gently air-dry for 5 s; Light cure for 20 s |
| T-SEP   | Transbond Self            | 3M/ESPE, St.          | Rub primer on the tooth for 5s; Gently air-dry for 5 s; Light cure for 20 s |
| (manufacturer recommendation) | Etching Primer (SEP)    | Paul, MN, EUA       | Light cure for 20 s                                               |
| SBU-20  | Single Bond               | 3M/ESPE, St.          | Rub primer on the tooth for 20s; Gently air-dry for 5 s Light cure for 20 s |
| (manufacturer recommendation) | Universal (SBU)         | Paul, MN, EUA       | Light cure for 20 s                                               |
| SBU-40  | Single Bond               | 3M/ESPE, St.          | Rub primer on the tooth for 40s; Gently air-dry for 5 s Light cure for 20 s |
|         | Universal (SBU)           | Paul, MN, EUA       | Light cure for 20 s                                               |

**SBS analysis**

The SBS was carried out as specified in ISO 11405, using a universal test machine (EMIC, DL2000, São José dos Pinhais, PR, Brasil) with a chisel at a crosshead speed of 0.5 mm/min until failure. The force required to debonding the bracket was recorded in Newtons (N) and was divided by the area of the base of the bracket (mm²) and converted to Mega Pascal (MPa) (Jacker-Guhr et al., 2019).

**ARI analysis**

After the brackets were debonded, the enamel surface of each tooth was examined under 12.5x magnification using a stereomicroscope (Leica TCS-SL; Leica, Wetzlar, Germany) to determine the amounts of residual adhesive remaining on each tooth. To determine the ARI, specimens were digitally photographed, standardized in relation to scanner light level, contrast, exposure and saturation. The files were exported in JPEG format and analyzed by a single calibrated examiner —ImageJ 1.50i software (National Institutes of Health, USA). The ARI assessment was performed in darkness by a single and previously trained and calibrated examiner (kappa intra-examiner analysis = 1.0).

The ARI was used to classify the failure modes as follow (Artun & Bergland, 1984): score 0: no composite resin left on the dental tooth; score 1: less than half of the composite resin left on the dental tooth; score 2: more than half of the composite resin left on the dental tooth; and score 3: all composite resin left on the dental tooth, with a clear impression of the bracket mesh.

**Morphological Analysis of the Enamel**

Ten teeth of each group were randomly selected, removed from the PVC cylinders. Dental fragments were dehydrated in different ethanol concentrations (i.e., 70, 80, 90, and 100%) and placed in a blue silica container for 24 hours. The dental sections were fixed on metal stubs with double-sided adhesive carbon tape (Electron Microscopy Science) and sputter coated with gold/palladium (SCD 050; Balzer, Schaan, Liechtenstein). Morphological analyses of the enamel (after debonding) were carried out with a scanning electron microscope (SEM, JEOL JSM 6610 LV), operated at 20 kV, with a working distance of 15 mm and a spot size of 53. Magnification (×200) was used to obtain representative images from the debonding surface. In representative regions were used x2000 of magnification.

**Statistical Analysis**

The normality and homoscedasticity of the data were analyzed by the Kolmogorov-Smirnov test. Shear bond strength data were compared with one-way ANOVA and Tukey’s post-hoc test ($P < 0.05$). The Kruskal–Wallis test was used to compare the ARI scores between the tested groups ($P < 0.05$). All analyses were performed using the software SPSS® 14.0 for Windows® (SPSS Inc., Chicago, IL, USA).

**3. Results**

The SBS between groups was significant different ($P < 0.001$). T-SEP (16.92 ± 3.45 MPa) and P-XT (17.27 ± 3.63 MPa) showed higher shear bond strength than SBU-20 (10.94 ± 3.24 MPa) and SBU-40 (8.41 ± 2.62 MPa) (Table 2).
Table 2. Descriptive statistics and ANOVA results and Tukey test for resistance (MPa).

| Groups    | Mean  | Standard-deviation |
|-----------|-------|--------------------|
| P-XT      | 17.3^A| 3.6                |
| T-SEP     | 16.9^A| 3.4                |
| SBU-20    | 10.9^B| 3.2                |
| SBU-40    | 8.4^B | 2.6                |

* Different letters represent statistically significant differences by the Tukey test. Source: Personal archives (2021).

It was not observed a significant difference between the groups according to the ARI distribution (Figure 1, Kruskal-Wallis test, $P = 0.062$). The score 1 (less than half of resin composite bonded to teeth) was the most frequent in all tested groups.

**Figure 1.** Distribution of ARI scores according to groups.

SEM analysis showed that enamel damage was detected in T-SEP (Figure 2) and P-XT (Figure 3) groups. This is observed within the erosion zones formed by phosphoric acid (Figures 2 and 3).
Figure 2. Photomicrography of SEP-5 group.

Enamel erosion zones formed by phosphoric acid are shown (area between the red arrows). Source: Personal archives (2021).

Figure 3. Photomicrography of P-XT group, demonstrated the presence of erosion zones.

4. Discussion

Our study showed that the conventional etch-and-rinse adhesive system, P-XT, and its self-etching version, T-SEP, produced a greater enamel bond strength than when using the universal adhesive SBU. Thus, our first null hypothesis must be rejected.

Previous studies also reported similar bracket-to-enamel SBS for P-XT and its self-etching version T-SEP (Seeliger et al., 2017, Yadala et al., 2014). T-SEP was delivered to the market for brackets bonding; however, it has the same chemical composition of Prompt-L-Pop —indicated for bond direct resin restorations. This adhesive presents the same acidity as phosphoric acid (pH ≈ around 1), producing also the same etching patterns (Di Hipólito et al., 2005). This acidity justifies the similar immediate bond values found for P-XT and T-SEP.

The SBS can be affected by different variables, such as adhesive composition, etching time, acidity of the etchant and brackets design (Ciocan et al., 2014). The prolonged application of universal adhesives is recognized as a viable alternative to increase the etching time and by consequence resin–enamel bond strength (Loguercio et al., 2015). This approach increases the contact of acidic resin monomers to enamel surface, creating a stable retentive pattern (Cardenas et al., 2017). Despite some authors reported improved enamel bond strength using these techniques —this is not consensual. It seems that other factors, such as the adhesive pH, as well as the application technique for each adhesive may have influenced the bond strength (Kimmes et al., 2010, Shafiei et al., 2019).

In this context, self-etching adhesives are classified according to their pH in 'ultra-mild' (pH > 2.5); 'mild' (pH ≈ 2); 'intermediately strong' (pH ranging from 1 to 2); 'strong' (pH ≤ 1) SBU is an 'ultra-mild' self-etching adhesive (i.e., pH = 2.7) (Almosa & Zafar, 2018). SBU has a lower enamel etching potential compared to other types (Van Meerbeek et al., 2011). This fact could explain the lower immediate SBS of SBU to intact enamel. On the other hand, based on our results, we observed that, even though the SBU greater application time with the intact bovine enamel was not enough to promote greater retention with the bracket.

Regarding the ARI distribution between all groups showed no significant differences, thus, the second hypothesis has to be accepted. The score 1 (less than 50% of resin composite bonded to teeth) was the most frequent in all groups, as found previously (Rodríguez-Chávez et al., 2017). The advantage of this feature is that minimum amounts of resin are adhered to the
enamel after debonding, reducing the required time to remove the residual adhesive. In the contrary, some reports suggested a potential enamel damage during debonding (Bosco et al., 2020), because its composition may promote more enamel damage when SBS values are higher (Cruz-González & Delgado-Mejía, 2020).

Even though T-SEP and PTX presented higher SBS, they produced greater enamel damage after debonding, when compared with the other groups (SBU-20, SBU-40). While adequate bonding of a multibracket appliance seems to be critical for complication-free treatment, the integrity of the enamel surface after debonding is very important too, to dentists and patients. It has been suggested that the minimum SBS of 6.0 to 8.0 MPa is adequate for bonding orthodontic brackets to teeth, which ensures that the bracket-adhesive-tooth bond remains intact (Mohammadi et al., 2018). As SBU is an 'ultra-mild' self-etch adhesive, it has a more superficial interaction than 'mild', 'intermediately strong', and 'strong'. This interaction occurs with dental substrate, and it is called "nano-interaction" (Carrilho et al., 2019). The ultra-mild interaction could explain the low damage caused by the SBU adhesive to enamel.

On the contrary, the phosphoric acid techniques are associated with a risk of enamel cracking during debonding, due to the aggressive etching pattern and the high adhesive penetration (Cehreli et al., 2005). However, the lower adhesive penetration was produced by T-SEP when 37% phosphoric acid and a separate primer were used (Cehreli et al., 2005). When T-SEP was compared to SBU, a great discrepancy was observed. The interaction of T-SEP with the enamel is micrometric (between 1 and 2µm) and for SBU is nanometric (few hundreds of nanometers) (Van Meerbeek et al., 2011) — justifying the lower damage for SBU. Furthermore, the SBU adhesive, contains a functional monomer, called 10-methacryloyloxydecyl dihydrogen phosphate or 10-MDP, whose molecules and the polyalkenoic acids (as functional polymer in glass-ionomers) chemically bond to Ca+ of HAp. The chemical reaction between these components form stable calcium phosphate and calcium carboxylate salts, respectively, along with only a limited surface-decalcification effect (Tian et al., 2017). In addition to reducing the number of operative steps SBU may reduce the equipment costs in orthodontics, and less materials are required to achieve equally effective adhesive bond strengths. Eliminating the acid etching followed by bonding, the risk of errors during application and the amount of chair time may be reduced (Cehreli et al., 2005).

In the present study, SBS of SBU adhesive ranged around 10 MPa. Based on security values for SBS (6 MPa and 8 MPa) (Alshahrani et al., 2018), it is possible to affirm that, that SBU offers adequate resistance to orthodontic forces and less risk of damage to the enamel in case of debonding. Future investigations on the SBU adhesion strength, for more time, and in clinical tests, could provide further insights to explain whether brackets bonded to teeth enamel will endure orthodontic forces.

5. Conclusion

The application of universal adhesives in the time recommended by the manufacturer ensure satisfactory bond strength and enamel integrity. Conventional P-XT and T-SEP adhesives had the highest shear bond strength, but they were associated with more enamel damage compared to universal adhesives.
