Background: Mitochondrial calcium overload triggers permeability transition pore formation, fatty acid release, and necrotic cell death.

Results: Pyrrophene and KT195 inhibit cell death by blocking mitochondrial calcium uptake.

Conclusion: Serine hydrolase inhibitors block mitochondrial calcium uptake but do not directly inhibit the enzyme releasing fatty acids during pore formation.

Significance: Serine hydrolase inhibitors have potential to block necrotic cell death associated with disease.

Perturbation of calcium signaling that occurs during cell injury and disease, promotes cell death. In mouse lung fibroblasts A23187 triggered mitochondrial permeability transition pore (MPTP) formation, lactate dehydrogenase (LDH) release, and necrotic cell death that were blocked by cyclosporin A (CsA) and EGTA. LDH release temporally correlated with arachidonic acid release but did not involve cytosolic phospholipase A2 (cPLA2α) or calcium-independent PLA2. Surprisingly, release of arachidonic acid and LDH from cPLA2α-deficient fibroblasts was inhibited by the cPLA2α inhibitor pyrrophene, and another serine hydrolase inhibitor KT195, by preventing mitochondrial calcium uptake. Inhibitors of calcium/calmodulin-dependent protein kinase II, a mitochondrial Ca2+ uniporter (MCU) regulator, also prevented MPTP formation and arachidonic acid release induced by A23187 and H2O2. Pyrrophene blocked MCU-mediated mitochondrial calcium uptake in permeabilized fibroblasts but not in isolated mitochondria. Unlike pyrrophene, the diacylglycerol analog 1-oleoyl-2-acetyl-sn-glycerol and CsA blocked cell death and arachidonic acid release not by preventing mitochondrial calcium uptake but by inhibiting MPTP formation. In fibroblasts stimulated with thapsigargin, which induces MPTP formation by a direct effect on mitochondria, LDH and arachidonic acid release were blocked by CsA and 1-oleoyl-2-acetyl-sn-glycerol but not by pyrrophene or EGTA. Therefore serine hydrolase inhibitors prevent necrotic cell death by blocking mitochondrial calcium uptake but not the enzyme releasing fatty acids that occurs by a novel pathway during MPTP formation. This work reveals the potential for development of small molecule cell-permeable serine hydrolase inhibitors that block MCU-mediated mitochondrial calcium overload, MPTP formation, and necrotic cell death.

Cells undergo a number of death pathways such as apoptosis, necroptosis, necrosis, and autophagic forms (1). Different forms of cell death are distinguished by morphological characteristics, requirement for ATP, gene expression, and unique biochemical pathways although there is considerable heterogeneity and overlap. Apoptosis occurs during normal developmental processes and is important in tissue homeostasis (2). Necrosis is a prevalent form of cell death that contributes to the pathogenesis of a variety of diseases such as neurodegenerative disorders, cardiac disease, and cancer (3–5).

Cell injury and death are often associated with dysfunctional calcium signaling (6–8). Perturbations in calcium homeostasis and mitochondria function contribute to necrotic cell death (9). Primary necrosis is driven by oxidative stress and calcium overload of the mitochondria that triggers formation of the mitochondrial permeability transition pore (MPTP),2 a non-selective reversible pore in the inner mitochondrial membrane (10). MPTP formation is inhibited by cyclosporin A (CsA), which targets cyclophilin D, a mitochondrial peptidyl prolyl isomerase (11). Although the molecular identity of the MPTP has not been resolved, cyclophilin D is a critical regulator of pore formation and necrotic cell death (10, 12, 13). The MPTP has a physiolog-

2 The abbreviations used are: MPTP, mitochondrial permeability transition pore; ABHD6, abhydrolase domain containing 6; ABPP, activity based protein profiling; autocamtide, autocamtide-2-related inhibitory peptide; CaMKII, calcium/calmodulin-dependent protein kinase II; cPLA2α, cytosolic phospholipase A2α; CsA, cyclosporin A; iPLA2γ, calcium-independent PLA2γ; LDH, lactate dehydrogenase; MGLL, monoglyceride lipase; MCU, mitochondrial calcium uniporter; MLF, mouse lung fibroblasts; IMLF, immortalized MLF; OAG, 1-oleoyl-2-acetyl-sn-glycerol; DAG, diacylglycerol; DMSO, dimethyl sulfoxide; Z-VAD(OMe)-fmk; N-Benzoyloxycarbonyl-Val-Ala-Asp(O-Me) fluoromethyl ketone.
Serine Hydrolase Inhibitors Block Necrotic Cell Death

Regulation of mitochondrial Ca\(^{2+}\) homeostasis, however, its irreversible opening occurs in response to extreme environmental insults or during disease resulting in mitochondrial swelling, depolarization, ATP depletion, and plasma membrane permeabilization (10, 14). For example, MPTP formation and necrotic cell death due to calcium accumulation and oxidative stress contribute to ischemia/reperfusion injury of the heart and other organs (9, 10). By blocking MPTP formation, CsA protects from myocardial reperfusion injury (15, 16). The MPTP may also contribute to the pathogenesis of chronic diseases such as neurological disorders and heart failure (17).

Although necrosis was historically considered to be “accidental” from exposure to harsh treatments, there is now evidence that it can be a regulated process. A number of signaling pathways have been identified that regulate MPTP formation and necrosis (18). Excessive activation of calcium/calmodulin-dependent protein kinase II (CaMKII) promotes mitochondrial calcium uptake and MPTP formation, which contribute to ischemia reperfusion injury and myocardial death (19, 20). A number of downstream targets for CaMKII have been identified including the mitochondrial calcium uniporter (MCU), which is phosphorylated and activated by CaMKII (20). The MCU is a 40-kDa calcium channel in the inner mitochondrial membrane responsible for ruthenium red/RU360-sensitive calcium uptake into the mitochondria (21, 22). Recent identification of the MCU provides an important pharmacologic target for development of inhibitors to prevent the deleterious consequences of excess mitochondrial calcium (23, 24).

Activation of phospholipases A\(_2\) (PLA\(_2\)) is implicated in regulating MPTP formation because release of fatty acids accompanies MPTP formation in isolated mitochondria, and can facilitate pore opening (25–27). There is evidence that calcium-independent PLA\(_2\) (iPLA\(_2\), which localizes to mitochondria, regulates MPTP formation based on the use of the iPLA\(_2\) inhibitor bromoeno lactone and using mitochondria from iPLA\(_2\) knock-out mice (28–31). The Group IVA cytosolic PLA\(_2\) (cPLA\(_2\)) is also suggested to regulate MPTP formation and cell death by releasing arachidonic acid (32, 33). Calcium regulates cPLA\(_2\) by promoting its translocation from the cytosol to intracellular membranes although there is no evidence that it localizes to mitochondria (34, 35).

In this study we investigated if cPLA\(_2\) played a role in regulating MPTP formation and cell death in lung fibroblasts by using the cPLA\(_2\) serine hydrolase inhibitor pyrrophenone and comparing fibroblasts from cPLA\(_2\) wild type and knock-out mice. We found that A23187 stimulates a similar cell death pathway in cPLA\(_2\) wild type and knock-out lung fibroblasts with characteristics of primary necrosis including mitochondrial calcium overload, cyclophilin D-dependent MPTP formation, and regulation by CaMKII. Although A23187-stimulated MPTP formation is accompanied by fatty acid release it does not involve either cPLA\(_2\) or iPLA\(_2\). However, cell death and fatty acid release in A23187-stimulated fibroblasts lacking cPLA\(_2\) are prevented by serine hydrolase inhibitors, pyrrophenone, and the triazole urea inhibitor KT195. The inhibitors act by blocking calcium loading of the mitochondria but do not directly inhibit fatty acid release that occurs by a novel pathway during MPTP formation (Fig. 12).

**EXPERIMENTAL PROCEDURES**

Materials—[5,6,8,9,11,12,14,15,\(^{2}\text{H}\)]Arachidonic acid (specific activity 100 Ci/mmol), [\(^{1}\text{C}\)]linoleic acid (specific activity 58.2 mCi/mmol), and [\(^{10}\text{C}\)]oleic acid (specific activity 26.3 Ci/mmol) were from PerkinElmer Life Sciences. Dubecco’s modified Eagle’s medium (DMEM) was from Lonza. Fetal bovine serum (FBS) was from Hyclone. Protease inhibitor tablets were from Roche Applied Science. Penicillin, streptomycin, l-glutamine, thapsigargin, Fura Red-AM, Rhod-2-AM, Mitotracker Green-FM, calcein-AM, Lipofectamine 2000, propidium iodide, Calcium Green-5N, probenecid, TaqMan Fast Universal PCR Master Mix, and TaqMan assay probes were from Invitrogen. A23187, RU360, CsA, autotcamtide-2-related inhibitory peptide II (autocamtide), and Z-VAD(OMe)-fmk were purchased from EMD Millipore. EGTA, imidazole, Heps, dithiothreitol, Fraction V BSA, hydrogen peroxide (H\(_2\)O\(_2\)) solution, and Tris-HCl were purchased from Sigma. The Qiagen RNeasy Minikit was used for RNA isolation. The Fermentas Maxima First Strand cDNA Synthesis Kit was from Thermo Scientific. The BCA protein assay kit was from Pierce. Pyrophophenone, bromoeno lactone, KML29, KN93, and KN92 were from Cayman Chemical Co. 1-Oleoyl-2-acetyl-sn-glycero (OAG) was from Avanti Polar Liquids. The PLA\(_2\) inhibitor Wyeth-1 was produced as previously described (36). The abhydrolase domain containing 6 (ABHD6) inhibitor KT195 and BODIPY-labeled probe HT-01 used for activity based protein profiling (ABPP) assays were synthesized as previously described (37).

**Preparation of Pyrrophenone-OH—**Pyrrophenone (100 \(\mu\)g) was dissolved in 60 \(\mu\)l of dry dimethylformamide and 200 \(\mu\)l of dry methanol. A small amount of sodium borohydride (a few crystals, \(~10\) \(\mu\)g) was added, and the mixture was stirred at room temperature for 2 h. Analysis by electrospray ionization mass spectrometry showed complete reduction of the ketone to the alcohol. The entire mixture was injected onto the C18 reverse-phase HPLC column (Waters, YMC-Pack ODS-A, 100 \(\times\) 20 mm, S-5 \(\mu\)m particles). The solvent program was 90% A (water), 10% B (acetonitrile) to 90% B over 25 min, then to 100% B over 30 s, then hold at 100% B for 10 min. The desired alcohol eluted at 15.4 min as confirmed by mass spectrometry and proton-NMR analysis. This program produces baseline separation of alcohol from ketone. The alcohol-containing fraction was concentrated to dryness under vacuum and then submitted to quantitative proton-NMR using N,N-dimethylformamide as an internal standard to determine the amount of alcohol.

**Generation of cPLA\(_2\)\(^{\xi}\) Knock-out Mice—**A conditional knock-out mouse of Group IVF PLA\(_2\) (cPLA\(_2\)\(^{\xi}\)) was generated by iNeous Targeting Laboratory, Inc. (Stony Brook, NY). A 12.5-kb region used to construct the targeting vector was first subcloned from a positively identified C57BL/6 BAC clone (RPC213) using homologous recombination. The region was designed such that the short homology arm extends 2.5 kb to 5’ of loxp/FRT flanked Neo cassette. The long homology arm ends on the 5’ single loxp site (\(~7.8\) kb long). The single loxp site was inserted upstream of exon 12, and the loxp/FRT-flanked Neo cassette inserted downstream of exon 12. The target region
heterozygous mice were mated to X-linked CMV-Cre mice wild-type mice. F2 heterozygous mice were identified for target confirmed by amplification and sequencing, and mated with cassette, and A3 (5\textsuperscript{GAGGCCACTTGTGTAGC-3\textsuperscript{G}}). Primer sets used to screen F1 mice include LAN1 (5\textsuperscript{G-CCAGGCCACTTGTGTAGC-3\textsuperscript{G}}), which anneals inside the Neo cassette, and A3 (5\textsuperscript{-AAGTCCTTCATGGGTGTGAGCTG-3\textsuperscript{G}}), which anneals 3' to the short homology arm, outside the region used to create the targeting construct. A3/LAN1 amplifies a fragment of 2.9 kb in length. The expanded positive ES cell clone was used as a positive control. An F1 heterozygous mouse was identified for targeted integration and the third loxP site confirmed by amplification and sequencing, and mated with wild-type mice. F2 heterozygous mice were identified for targeted integration and confirmed with the third loxP site. F2 heterozygous mice were mated to X-linked CMV-Cre mice (129-Gt(ROSA)26Sor\textsuperscript{pm1c/Cre/Esr1Nat\textsuperscript{f}}) to remove the loxP-flanked Neo cassette and exon 12 for generation of cPLA\textsubscript{2c} knock-out mice. F3 heterozygous CMV-Cre cPLA\textsubscript{2c} knock-out mice were mated to wild type C57BL/6 mice to generate mice without Cre and then heterozygous cPLA\textsubscript{2c} knock-out mice were backcrossed to wild type Balb/c mice for at least 10 generations to get cPLA\textsubscript{2c} knock-out Balb/c mice.

**Cell Culture and Fatty Acid Release Assay**—Mouse lung fibroblasts (MLF) were isolated from wild type cPLA\textsubscript{2c} (MLF\textsuperscript{+/+}) or cPLA\textsubscript{2c} (MLF\textsuperscript{−/−}), and knock-out cPLA\textsubscript{2c} (MLF\textsuperscript{−/-}) or cPLA\textsubscript{2c} (MLF\textsuperscript{−/−}), mice using lung tissue explants as previously described (38). Primary MLF were used between 4 and 6 passages. SV40 immortalized MLF\textsubscript{α} (IMLF\textsuperscript{−/-}) and MLF\textsuperscript{−/-}) were generated as previously described (39). MLF (0.5 \times 10^6 cells/cm\textsuperscript{2}) and IMLF (1.25 \times 10^6 cells/cm\textsuperscript{2}) were plated in 250 µl of DMEM containing 10% FBS, 0.1% nonessential amino acids, 1 mM sodium pyruvate, 100 units/ml of penicillin, 100 µg/ml of streptomycin, 0.29 mg/ml of glucose (growth media) in 48-well plates. After incubation for 24 (MLF) or 6 h (IMLF) in 5% CO\textsubscript{2} at 37 °C, cells were washed with, and incubated in, serum-free DMEM (250 μl) containing 0.1% BSA (stimulation media) and 0.1 μCi of [\textsuperscript{3}H]arachidonic acid, [\textsuperscript{3}H]oleic acid, or [\textsuperscript{3}C]linoleic acid. Cells were incubated overnight, washed twice, and fresh stimulation media added. Cells were stimulated with 1 µg/ml of A23187 for 30 min or for the times indicated. In experiments to determine the effect of H\textsubscript{2}O\textsubscript{2} on fatty acid release and cell death, MLF were incubated in stimulation media containing 0.1 μCi of [\textsuperscript{3}H]arachidonic acid for 6 h, washed, and then treated with 1 mM H\textsubscript{2}O\textsubscript{2} for 18 h. Inhibitors were added 30 min before stimulation or as indicated.

To measure the amount of fatty acid released, the culture medium was collected after stimulation, centrifuged for 10 min at 13,000 \times g, and the radioactivity in the supernatant determined. Floating cells recovered in the pellet after centrifuging the culture medium were solubilized with 0.1% Triton X-100 and combined with the adherent cells remaining in the well to determine the total cell-associated radioactivity. The amount of [\textsuperscript{3}H]arachidonic acid released into the culture media was calculated as a percentage of total radioactivity (cells plus media) in each well. In separate control experiments, the culture medium was extracted according to Bligh and Dyer (40), and the radioactivity was confirmed to migrate as free fatty acid when analyzed by thin-layer chromatography (41).

**Cell Death Assays**—As a measure of cell death the level of LDH released into the culture medium was determined. The culture medium collected from the fatty acid release assays after centrifugation as described above was assayed (50 µl) using the Cyto-Tox ONE homogeneous membrane integrity assay kit (Promega) according to the manufacturer’s protocol using an LS55 spectrophotometer (PerkinElmer Life Sciences). The level of LDH released into the medium was expressed as a percentage of total cellular LDH. Cell death was also evaluated using propidium iodide staining. IMLF\textsuperscript{−/-} were stimulated with A23187 for the times indicated followed by staining with 0.5 µg/ml of propidium iodide. Images were captured on a Marinas 200 spinning disk confocal microscope using 561/617 nm excitation/emission using Intelligent Imaging Innovation Inc. (31) software (Slidebook 5.0).

**Silencing of Abhd6**—Retroviral plasmids (pGFP-V-NS) containing four Abhd6 specific or scrambled negative control (TR30013) shRNAs were prepared as described by the manufacturer’s protocol (Origene). To produce retroviruses, Gryphon retroviral packaging cells (Allele Biotechnology) were transfected with retroviral expression plasmids using Lipofectamine 2000 and incubated for 48 h. The culture media containing the retroviruses were collected and centrifuged at 2000 \times g for 5 min. IMLF\textsuperscript{−/-} were incubated in the culture media containing the retroviruses and stable cell lines expressing shRNAs were selected using 10 µg/ml of puromycin according to the manufacturer’s protocol. The most effective shRNA for silencing Abhd6 was identified (GIS70346) by comparing levels of Abhd6 mRNA using real-time PCR. Clones were isolated by limiting dilution and knockdown confirmed by real-time PCR and by ABPP assay for determining ABHD6 activity in membrane proteomes as described below.

**ABPP Assay for ABHD6**—IMLF\textsuperscript{−/-} were plated at 1 \times 10^4 cells/cm\textsuperscript{2} in growth media, incubated for 24 h in 5% CO\textsubscript{2} at 37 °C, then washed and incubated overnight in serum-free DMEM containing 10% FBS. Cells were treated with inhibitors KT109, KT195, or pyrophosphate for 30 min at 37 °C, washed twice with ice-cold PBS, then harvested and lysed in PBS by sonication at 4 °C. Lysates were centrifuged at 100,000 \times g for 4 h. The membrane pellet (proteome) was resuspended in PBS by sonication and the protein concentration was determined by BCA assay. Proteome samples (50 µg of protein in 50 µl of total reaction volume) were incubated with 1 µM HT-01 for 30 min at 37 °C. In some experiments the proteomes were prepared from untreated cells and then incubated with inhibi-
Serine Hydrolase Inhibitors Block Necrotic Cell Death

tors in vitro prior to adding the probe. SDS-PAGE loading buffer was added and the samples boiled for 10 min. After separation by SDS-PAGE (10% acrylamide), bands were visualized by in-gel fluorescence scanning using a Typhoon FLA 9500 (GE Healthcare).

Real-time PCR—RNA was isolated from MLF and IMLF, treated with DNase to remove contaminating genomic DNA, and cDNA generated using 1 μg of RNA. PCR contained 10 μl of 2 × TaqMan fast universal master mixture, 1 μl of 20X TaqMan assay/probe, and 9 μl of cDNA (75–100 ng) in RNase-free water. The Thermal Fast cycle program was: 20 s at 95 °C followed by 40 cycles of 1 s at 95 °C and 20 s at 60 °C using the StepOne Plus real-time PCR system (Applied Biosystems). Triplicate reactions were analyzed for each sample. TaqMan assay probes to determine mRNA expression for the enzymes monoglyceride lipase (MGLL) (Mgl2 Mm 00449274_m1), β-glucuronidase (Gusb Mm01197698_ml), and ABHD6 (Abhd6 Mm00481199_ml) were used. The housekeeping gene Gusb was used for normalization. For analysis of Mgl2 expression a calibrator containing a mixture of RNA from IMLF/H9251, IMLF/H9252, and IMLF/H9262 was used for normalization. Threshold cycle values (Cq) were determined and used for 2ΔΔCq analysis of relative gene expression (42).

Calcium Imaging—IMLFα−/− were plated at 1 × 104 cells/cm² in growth media in glass-bottomed MatTek plates and incubated overnight. Cells were loaded at 37 °C with Fura Red-AM (5 μM) for 15 min to measure cytosolic calcium, and with Rhod-2-AM (1 μM) together with MitoTracker Green (0.5 μM) for 10 min to measure the mitochondrial calcium, in the presence of 0.02% pluronic acid F-127. After washing, cells were incubated for 30 min at 37 °C in phenol red-free stimulation medium containing 25 mM Hepes, pH 7.4, and 2 mM probenecid followed by incubation with inhibitors (or DMSO) for 30 min (or as indicated). After adding A23187 (1 μM/ml) images were captured every 5 s for Fura Red-loaded cells and every 20 s for Rhod-2-loaded cells. Microscopy was conducted at 37 °C on an inverted Zeiss 200M microscope driven by Intelligent Imaging Innovations Inc. (3I) software (Slidebook 5.0).

Calcium Uptake and Swelling Assays in Isolated Mitochondria—Mitochondria were prepared as described previously (44). Confluent IMLFα−/− (10, 150-mm dishes) were trypsinized and washed with PBS. Cells were homogenized in mitochondria isolation buffer (225 mM mannitol, 75 mM sucrose, 0.1 mM EGTA, 30 mM Tris-HCl, pH 7.4) with a Teflon homogenizer and the homogenate was centrifuged for 5 min at 600 × g at 4 °C. The supernatant was collected and centrifuged for 10 min at 7,000 × g. The pellet was resuspended in mitochondrial isolation buffer without EGTA and centrifuged for 10 min at 12,000 × g. The mitochondrial pellet was resuspended in isolation buffer and protein content was determined. Mitochondrial calcium uptake was assayed by monitoring the decrease in extramitochondrial calcium using the fluorescent indicator Calcium Green-5N. Isolated mitochondria (0.1 mg/ml) were incubated in 100 μl of assay buffer (5 mM MOPS, 120 mM KCl, 5 mM KH2PO4, 5 mM glutamate, 5 mM malate, 5 mM succinate, pH 7.4) containing 1 μM Calcium Green-5N. After addition of calcium (25 μM) changes in fluorescence at 488/532 nm excitation/emission were measured. Mitochondrial swelling that occurs during calcium-induced MPTP formation in isolated mitochondria was assayed by monitoring a decrease in mitochondrial light scattering. Isolated mitochondria were incubated in 200 μl of assay buffer and the decrease in absorbance at 530 nm to measure swelling was monitored after addition of calcium (25 μM). To test the effect of inhibitors on calcium uptake and swelling, mitochondria were incubated with inhibitors for 5 min before calcium addition. Recordings were made every 1 min at room temperature in 96-well plates using a Wallac Victor2 1420 Multilabel Counter. Assays were adapted from protocols as described (45).

Statistical Analysis—Statistics were calculated in GraphPad using unpaired t test to obtain two-tailed p values.
Serine Hydrolase Inhibitors Block Necrotic Cell Death

**RESULTS**

**Arachidonic Acid Release That Accompanies A23187-stimulated Necrotic Cell Death in Lung Fibroblasts Is Not Mediated by cPLA₂ or iPLA₂**—MLF isolated from cPLA₂α⁺/⁺ and cPLA₂α⁻⁻ mice, then immortalized with SV40 (IMLF), were used to investigate if cPLA₂α activation and arachidonic acid release regulate necrotic cell death. IMLFa⁺/⁺ and IMLFa⁻⁻ were treated with the calcium ionophore A23187, which is a well described inducer of necrotic cell death due to cellular calcium overload and MPTP formation resulting in plasma membrane rupture and LDH release (10, 46). We previously reported that A23187 stimulated [³H]arachidonic acid release from IMLFa⁺/⁺ and to a lesser extent from IMLFa⁻⁻, but we had not monitored cell death (38). A23187 stimulated release of LDH to a similar extent in IMLFa⁺/⁺ and IMLFa⁻⁻ excluding a role for cPLA₂α (Fig. 1a). CsA and chelating extracellular calcium with EGTA inhibited LDH release in both cell lines consistent with a role for cyclophilin D-dependent MPTP formation due to calcium overload (Fig. 1a). CsA also inhibited arachidonic acid release from IMLFa⁺/⁺ and to a slightly greater extent from IMLFa⁻⁻ (Fig. 1b). The effect of A23187 concentration and incubation time on arachidonic acid release and cell death was determined to further probe the relationship between these processes in IMLFa⁻⁻. There was a concentration-dependent increase in arachidonic acid release from IMLFa⁻⁻ that correlated with LDH release (Fig. 1c). The time course of arachidonic acid release also correlated with LDH release occurring most rapidly from 10 to 30 min after addition of A23187 (Fig. 1d). Similar results were also obtained with the calcium ionophore, ionomycin (data not shown). The data suggest that A23187-stimulated cell death and arachidonic acid release in lung fibroblasts requires extracellular calcium and is mediated by cyclophilin-D-dependent MPTP formation but does not involve cPLA₂α.

**Serine Hydrolase Inhibitors Block Arachidonic Acid Release, MPTP Formation, and Cell Death**—We previously reported that arachidonic acid release from A23187-stimulated IMLFa⁺/⁻ was unexpectedly inhibited by two structurally different cPLA₂α inhibitors (pyrrophenone and Wyeth-1) (41). These serine hydrolase inhibitors also blocked LDH release from A23187-stimulated IMLFa⁺/⁻, but the iPLA₂ inhibitor bromoenolactone was ineffective (Fig. 2a). We investigated the effect of the inhibitors on A23187-stimulated MPTP formation using an established method that monitors calcine fluorescence in mitochondria (47). Cells are loaded with calcine-AM, which is de-esterified in the cytosol and then diffuses into cellular organelles including the mitochondria. Cobalt is added, which quenches calcine fluorescence in all compartments except the mitochondria (47). Cells are loaded with calcine-AM, which is de-esterified in the cytosol and then diffuses into cellular organelles including the mitochondria. Cobalt is added, which quenches calcine fluorescence in all compartments except the mitochondria. We investigated the effect of the inhibitors on A23187-stimulated MPTP formation using an established method that monitors calcine fluorescence in mitochondria (47). Cells are loaded with calcine-AM, which is de-esterified in the cytosol and then diffuses into cellular organelles including the mitochondria. Cobalt is added, which quenches calcine fluorescence in all compartments except the mitochondria where it is excluded. When MPTP formation is blocked, cobalt gains access to the mitochondria and quenches calcine fluorescence. As shown in Fig. 2b, there was a decrease in mitochondrial calcine fluorescence in A23187-treated IMLFa⁺/⁻, consistent with MPTP formation, which was inhibited by pyrrophenone, Wyeth-1, and CsA. The bright field images show...
Serine Hydrolase Inhibitors Block Necrotic Cell Death

The effect of A23187 on cell morphology consistent with cell death and protection by inhibitors that block MPTP formation. Wyeth-1 inhibited release of arachidonic acid and LDH at 10 μM but it was a weaker inhibitor (IC_{50} ~ 4 μM) than pyrophosphate (IC_{50} ~ 0.5 μM) and it was not further used.

Cell death was also evaluated by staining IMLFα−/− with the vital dye propidium iodide, which is taken up by cells when the integrity of the plasma membrane is disrupted. There was an increase in propidium iodide staining after A23187 treatment that occurred over a similar time frame as the release of LDH (Fig. 2c). Propidium iodide staining was inhibited by pyrophosphate but was not affected by the pan-caspase inhibitor Z-VAD(Ome)-fmk (Fig. 2d). The rapid induction of LDH release and propidium iodide staining, and lack of caspase involvement, suggests that A23187 induces primary necrosis and not secondary necrosis following apoptosis.

A23187-stimulated Cell Death in Primary Lung Fibroblasts Is Not Mediated by cPLA_{2α} or cPLA_{2ζ}—The cell death pathway was also induced by A23187 in primary lung fibroblasts from cPLA_{2α}−/− (MLFα−/−) and cPLA_{2ζ}−/− mice (MLFζ−/−) (Fig. 3a). A23187 stimulated more arachidonic acid release from MLFζ−/− than MLFα−/−, but similar levels of LDH release, which were inhibited by CsA and pyrophosphate. The results indicate that cPLA_{2α} contributes to A23187-stimulated arachidonic acid release but not cell death. We previously reported that pyrophosphate inhibits mouse GIVF cPLA_{2ζ}, which has similar specific activity, inhibitor sensitivity, and calcium dependence as cPLA_{2ζ} (41). cPLA_{2ζ}−/− mice were generated and a comparison of MLFζ−/− and MLFα−/− showed no differences in the amount of arachidonic acid and LDH release, or responses to pyrophosphate and CsA, ruling out a role for cPLA_{2ζ} (Fig. 3b). A comparison of MLF from wild type and cPLA_{2α}/cPLA_{2ζ} double knock-out mice additionally confirmed that these PLAs do not mediate cell death induced by A23187 (data not shown).

Effect of Pyrophosphate and the Triazole Urea Inhibitor KT195 on A23187-stimulated Arachidonic Acid Release and Cell Death—An alternative pathway for arachidonic acid release involves the hydrolysis of arachidonic acid from the endocannabinoid 2-arachidonylglycerol by MGLL (48). This pathway is initiated by activation of diacylglycerol (DAG) lipases that hydrolyze the sn-1 acyl chain of DAG to form 2-arachidonylglycerol (49). Real-time PCR revealed that MLFα−/− and MLFζ−/− expressed higher levels of MGLL than cells expressing cPLA_{2α}, perhaps reflecting a compensatory response (Fig. 4a). We tested inhibitors of MGLL (KML29) and ABHD6 (KT195), another enzyme that hydrolyzes 2-arachidonylglycerol, to determine whether these serine hydrolases mediated A23187-stimulated arachidonic acid release from MLFα−/− (37, 50). The most effective inhibitors were the triazole urea ABHD6 inhibitor KT195 (IC_{50} ~ 0.7 μM) (Fig. 4b), and pyrrolidine-containing inhibitor pyrophosphate (IC_{50} ~ 0.5 μM) (Fig. 4c). Inhibition of arachidonic acid release and LDH release displayed very similar does responses. The MGLL inhibitor...
(KML29) had little effect on LDH and arachidonic acid release (Fig. 4b).

Pyrrophenone likely inhibits cPLA\textsubscript{2}a via formation of a hemiketal between its ketone carbonyl and the active site serine of the enzyme based on the ability of polarized ketones to form stable hemiketals with serine proteases and esterases (51–53). To provide support for this mechanism we tested the effect of pyrrophenone-OH in which the ketone was reduced to the secondary alcohol. Serum-stimulated arachidonic acid release from IMLFa\textsuperscript{−/−}, which is mediated by cPLA\textsubscript{2}a (41), was poorly inhibited by pyrrophenone-OH compared with pyrrophenone (IC\textsubscript{50} 0.05 \(\mu\)M) (Fig. 4d). Similarly pyrrophenone-OH was ineffective at blocking cell death and arachidonic acid release from IMLFa\textsuperscript{−/−} (Fig. 4c). The results suggest that pyrrophenone acts to prevent cell death by targeting a serine at the active site of an esterase or amidase.

ABPP assays were carried out to determine whether there was a correlation between concentrations of KT195 and pyrrophenone that inhibited cell death and arachidonic acid release, with concentrations that inhibited ABHD6 in cells. IMLFa\textsuperscript{−/−} were treated with KT195 and pyrrophenone, followed by preparation of membrane proteomes that were probed with BODIPY-labeled HT-01 to detect ABHD6 (37). The effect of the inhibitors added directly to the proteome in vitro was also tested. The ABPP assay in IMLFa\textsuperscript{−/−} proteome showed strong reactivity of ABHD6 (~35 kDa) with the BODIPY-labeled HT-01 probe detected by in-gel fluorescence scanning (Fig. 5, a and b). Pyrrophenone added in situ or added to the proteome in vitro prior to adding the probe did not block the binding of HT-01 to ABHD6 indicating that it does not inhibit this serine hydrolase (Fig. 5a). However, binding of HT-01 to ABHD6 was completely blocked by pre-treating IMLFa\textsuperscript{−/−} with 0.2–2 \(\mu\)M KT195 in situ (Fig. 5b), which is not unexpected because the IC\textsubscript{50} of KT195 for ABHD6 in other cells is less than 0.2 \(\mu\)M (37). When added directly to the proteome in vitro KT195 showed a dose-dependent inhibition of HT-01 binding to ABHD6 with an IC\textsubscript{50} of ~25 nm (Fig. 5b). The fact that 0.2 \(\mu\)M KT195, and even higher concentrations of KML29, had little effect on release of arachidonic acid and LDH from IMLFa\textsuperscript{−/−} suggests that neither MGLL nor ABHD6 play a role in mediating arachidonic acid release and cell death in IMLFa\textsuperscript{−/−} in response to A23187.

Further evidence that ABHD6 does not mediate A23187-stimulated fatty acid release and cell death was provided by results using shRNA knockdown of Abhd6 (Fig. 5). We selected stable clones of IMLFa\textsuperscript{−/−} after transfection with retrovirus containing Abhd6 shRNA and identified a clone with significant reduction (~70%) in Abhd6 mRNA expression compared with a clone expressing control shRNA (Fig. 5c). ABPP assays of proteomes from control and Abhd6 shRNA clones showed 70–80% decrease in BODIPY-labeled HT-01 binding compared with control consistent with reduced levels of ABHD6 protein in the Abhd6 shRNA clone (Fig. 5d). Despite ABHD6 knockdown, A23187-stimulated LDH and arachidonic acid release were not significantly different in control and Abhd6 shRNA expressing IMLFa\textsuperscript{−/−} and both were similarly inhibited by pyrrophenone and KT195 (Fig. 5e). The results suggest that ABHD6 does not play a role in mediating A23187-stimu-

![FIGURE 5. ABHD6 does not regulate A23187-induced cell death. The ability of pyrrophenone (Pyr) (a) or KT195 (b) to bind ABHD6 was determined by competitive ABPP assay of proteomes from IMLFa\textsuperscript{−/−} prepared as described under "Experimental Procedures." The serine hydrolase inhibitors were added at the indicated concentrations either to IMLFa\textsuperscript{−/−} in situ prior to preparing membrane proteomes, or added to the proteomes in vitro, followed by incubation with BODIPY-labeled HT-01 probe. Bands were visualized on SDS-polyacrylamide gels by in-gel fluorescence scanning. A representative experiment of 2–3 independent experiments is shown. c, knockdown of Abhd6 mRNA was determined by real-time PCR analysis of RNA from IMLFa\textsuperscript{−/−} stably expressing Abhd6 shRNA or scrambled negative control. d, knockdown of ABHD6 protein was determined by competitive ABPP assay of membrane proteomes from IMLFa\textsuperscript{−/−} stably expressing control or Abhd6 shRNA. The relative amount of BODIPY-labeled HT-01 probe binding to ABHD6 was determined by measuring the intensity of the fluorescent signal of the ABHD6 band on SDS-polyacrylamide gels using ImageQuant TL software (GE Healthcare) and expressed as the % of control. Results from two independent experiments (E1 and E2) are shown. e, IMLFa\textsuperscript{−/−} stably expressing control or Abhd6 shRNA were treated with 2 \(\mu\)M Pyr or 2 \(\mu\)M KT195 for 30 min, stimulated with A23187 for 30 min, and then the release of \(^{3}H\)arachidonic acid and LDH was determined. The results are from 3 independent experiments ± S.E.](1497)
Serine Hydrolase Inhibitors Block Necrotic Cell Death

Cytosolic and mitochondrial calcium were obtained with KT195 (Fig. 6b). We investigated the effect of washing the cells after the 30-min preincubation with pyrrophenone prior to adding A23187. Following washout of pyrrophenone, the increase in mitochondrial calcium was delayed for ~10 min after addition of A23187 but increased at 15–20 min to levels seen in A23187-stimulated cells not treated with inhibitor (Fig. 6c). Similar results were obtained with KT195 (data not shown). The washed cells were not protected from cell death, and released LDH and arachidonic acid 30 min after A23187 (Fig. 6d). The results show a direct correlation between mitochondrial calcium loading, cell death, and arachidonic acid release.

The results suggest that pyrrophenone and KT195 inhibit MPTP formation and cell death by preventing mitochondrial calcium overload, which has been shown to occur in cells treated with calcium ionophores through the MCU (46). As an alternative approach for inducing mitochondrial calcium loading and investigating the effect of pyrrophenone, digitonin-permeabilized IMLF α−/− were used. This approach also provided a system to test the effect of the MCU inhibitor RU360, which is not permeable in many cell types (54, 55). Incubating permeabilized IMLF α−/− in intracellular buffer containing calcium induced an increase in mitochondrial calcium, which was inhibited by pyrrophenone and by RU360 (Fig. 7a). We also measured calcium uptake and MPTP formation in isolated mitochondria from IMLF α−/− to determine whether the serine hydrolase inhibitors had a direct effect on mitochondria. Isolated mitochondria incubated in buffer containing the calcium indicator Calcium Green-5N showed calcium uptake as measured by a decrease in Calcium Green-5N fluorescence in the measured mitochondria incubated in buffer containing the calcium indicator Calcium Green-5N showed calcium uptake as measured by a decrease in Calcium Green-5N fluorescence in the buffer (Fig. 7b). Calcium uptake was completely blocked by the MCU inhibitor RU360 but was not blocked by pyrrophenone, KT195, or CsA.

MPTP formation in isolated mitochondria triggered by addition of calcium (25 μM) to the buffer was assayed by measuring absorbance at 530 nm, which decreases due to swelling of the mitochondria. A decrease in absorbance occurred for 15 min after adding calcium, which was blocked by RU360 and CsA, but not by pyrrophenone or KT195 (Fig. 7c). There was a significant reduction in calcium-induced mitochondrial swelling by RU360 and CsA as shown for the 10-min time point (Fig. 7c, bar graph). The data indicate that mitochondrial calcium uptake occurred through the MCU and triggered cyclophilin D-dependent MPTP formation. However, the serine hydrolase inhibitors did not have a direct effect on blocking calcium uptake in isolated mitochondria in contrast to the results using intact or permeabilized cells. Pyrrophenone has also been...
shown not to inhibit calcium-induced swelling of isolated mitochondria from mouse liver (31).

**CaMKII Regulates Cell Death**—We also tested the effect of CaMKII inhibitors on A23187-stimulated cell death and arachidonic acid release because CaMKII phosphorylates and enhances MCU function (20). The CaMKII inhibitors KN93, but not the inactive control KN92, and autocamtide dose dependently inhibited LDH and arachidonic acid release from IMLFα−/− stimulated with A23187 (Fig. 8, a and b). Using the calcine assay to monitor MPTP formation we found that autocamtide prevented the loss of calcine fluorescence from IMLFα−/− treated with A23187 suggesting that it inhibited cell death and arachidonic acid release by blocking MPTP formation (Fig. 8c). The results suggest that pyrophenone inhibits cell death by blocking calcium uptake in IMLFα−/− that is mediated by the MCU and is regulated by CaMKII (see Fig. 12).
Serine Hydrolase Inhibitors Block Necrotic Cell Death

FIGURE 9. Effect of OAG on A23187-stimulated release of arachidonic acid, cell death, and mitochondrial calcium uptake. a, IMLFα−/− were incubated with the indicated concentrations of OAG for 5 min, stimulated with A23187 for 30 min, and the release of [3H]arachidonic acid (left panels) and LDH (right panels) was determined (n = 3 ± S.E., *, p < 0.05 compared with A23187-stimulated IMLFα−/− without inhibitors). b, calcein-labeled IMLFα−/− were treated with vehicle (DMSO) or 250 μM OAG for 5 min and then stimulated with A23187 for 30 min. After adding cobalt, fluorescence microscopy was used to monitor calcein fluorescence in the mitochondria. Images are shown from a representative experiment and results confirmed in 2 independent experiments. c, IMLFα−/− were incubated with the indicated concentrations of OAG for 5 min, stimulated with A23187 for 30 min, and the release of [3H]arachidonic acid (left panels) and LDH (right panels) was determined (n = 3 ± S.E., **, p < 0.01 compared with A23187-stimulated IMLFα−/− without inhibitors, *, p < 0.01 compared with unstimulated IMLFα−/− without inhibitors). The effect of OAG (d) and CsA (e) on mitochondrial calcium uptake was determined in IMLFα−/− loaded with Rhod-2-AM/MitoTracker. Cells were treated with (hatched lines) or without (solid lines) 250 μM OAG or 10 μM CsA for 30 min then treated with A23187. As a control, the effect of OAG and CsA added to cells not treated with A23187 is shown (gray lines). Independent experiments are each represented by different color lines. The line traces are the average fold-changes over time in mitochondrial calcium from five individual cells after adding A23187 (time 0).

release in IMLFα−/− treated with and without A23187 (Fig. 9c, left panel), which is likely due to the ability of OAG to activate PKC, a known activator of cPLA2 (58–60). This is consistent with our previous findings that the PKC activator phorbol 12-myristate 13-acetate stimulates arachidonic acid release from IMLFα−/− and enhances responses to A23187 (38). However, in contrast to OAG, phorbol 12-myristate 13-acetate treatment of IMLFα−/− did not block the release of arachidonic acid or LDH in response to A23187 (38). Experiments were carried out to determine whether OAG blocked cell death in response to A23187 by inhibiting mitochondrial calcium uptake. In contrast to the serine hydrolase inhibitors, OAG enhanced mitochondrial calcium in A23187-stimulated IMLFα−/− (Fig. 9d). A similar increase in mitochondrial calcium occurred when A23187-stimulated IMLFα−/− were treated with CsA (Fig. 9e). By targeting cyclophilin D, CsA blocks calcium leakage from the MPTP resulting in enhanced mitochondrial calcium levels (46). The results suggest that OAG has a direct effect on blocking MPTP formation.

Fatty Acid Release Occurs during MPTP Formation—The ability of OAG and CsA to inhibit arachidonic acid release without blocking mitochondrial calcium uptake suggests that fatty acid release occurs during MPTP formation. This was tested by treating IMLFα−/− with a high concentration of thapsigargin, which induces MPTP formation by a direct effect on mitochondria that does not involve an increase in cytosolic calcium (61). Thapsigargin (20 μM) induced release of LDH and arachidonic acid from IMLFα−/− between 15 and 90 min after stimulation (Fig. 10a). A slightly lower concentration of thapsigargin (10 μM) was ~50% as effective and concentrations (<1 μM) that inhibit SERCA had no effect (data not shown). Thapsigargin also stimulated release of oleic acid and linoleic acid from IMLFα−/− (Fig. 10b), as we previously reported for A23187-stimulated IMLFα−/− (41). However, unlike A23187, the release of arachidonic acid and LDH induced by thapsigargin was not inhibited by pyrrophenone, KT195, KN93, or EGTA.
Serine Hydrolase Inhibitors Block Necrotic Cell Death

**FIGURE 10.** Thapsigargin-induced cell death and arachidonic acid release are inhibited by CsA and OAG but not by pyrophenone or EGTA. *a.* IMLFα−/− were treated with (circles) or without (triangles) 20 μM thapsigargin for the indicated times, and release of [3H]arachidonic acid (black symbols) and LDH (open symbols) was determined (n = 3 ± S.E.). *b.* IMLFα−/− labeled overnight with either [3H]oleic acid (18:1) or [14C]linoleic acid (18:2) were stimulated with (black bars) or without (open bars) 20 μM thapsigargin for 60 min and fatty acid release was determined (n = 3 ± S.E.). *c.* IMLFα−/− treated with CsA, bromoenolactone (Bel), EGTA, pyrophenone (Pyr), KN93, or KT195 for 30 min were stimulated with 20 μM thapsigargin for 60 min and the release of [3H]arachidonic acid (left panel) and LDH (right panel) was determined (n = 3 ± S.E., *p* < 0.0001 compared with thapsigargin-stimulated IMLFα−/− without inhibitors). *d.* IMLFα−/− were incubated with the indicated concentrations of OAG for 5 min, stimulated with thapsigargin for 60 min and the release of [3H]arachidonic acid (left panel) and LDH (right panels) was determined (n = 3 ± S.E., *p* < 0.05 compared with thapsigargin-stimulated IMLFα−/− without OAG).

(Fig. 10c). The iPLA2 inhibitor bromoenolactone also did not inhibit release of arachidonic acid or LDH. Importantly, the release of arachidonic acid and LDH stimulated by thapsigargin was inhibited by CsA (Fig. 10c) and OAG (Fig. 10d) suggesting that cell death induced by thapsigargin was due to MPTP formation. The results demonstrate that the serine hydrolase inhibitors prevent MPTP formation, fatty acid release, and cell death by blocking mitochondrial calcium loading but do not directly inhibit the enzyme responsible for fatty acid release that accompanies MPTP formation.

Serine Hydrolase Inhibitors Block Cell Death Induced by H$_2$O$_2$—To determine whether the serine hydrolase inhibitors blocked cell death triggered by other agents we tested their effect in fibroblasts treated with H$_2$O$_2$. A number of cell death pathways are triggered by H$_2$O$_2$ including necrotic cell death involving cyclophilin D-dependent MPTP formation (46, 62–64). The ability of H$_2$O$_2$ (1 mM) to stimulate release of arachidonic acid and LDH from MLF stimulated with H$_2$O$_2$, a. MLFα−/− (open bar) or MLFα−/− (black bar) were stimulated with 1 mM H$_2$O$_2$ for 18 h and release of [3H]arachidonic acid (left panel) and LDH (right panel) was determined. Cells were treated with CsA, pyrophenone (Pyr), KT195, or KN93 for 30 min prior to stimulation with H$_2$O$_2$. The results are from 3 independent experiments ± S.E. (*p* < 0.05 when compared with H$_2$O$_2$ stimulated MLFα−/− (*)) or MLFα−/− (**) without inhibitors). b. MLFα−/− were loaded with calcine prior to incubation with inhibitors for 30 min and then stimulated with 1 mM H$_2$O$_2$ for 18 h. The results are from 3 independent experiments ± S.E. (*, *p* < 0.0005 when compared with MLFα−/− without H$_2$O$_2$; **, *p* < 0.005 when compared with H$_2$O$_2$ stimulated MLFα−/− without inhibitors). Images showing the effect of inhibitors on calcine fluorescence in MLFα−/− treated with and without H$_2$O$_2$ (right panel) are from a representative experiment and results confirmed in 2 independent experiments.

**FIGURE 11.** Serine hydrolase inhibitors block release of arachidonic acid and LDH from MLF stimulated with H$_2$O$_2$. a. MLFα−/− (open bar) or MLFα−/− (black bar) were stimulated with 1 mM H$_2$O$_2$ for 18 h and release of [3H]arachidonic acid (left panel) and LDH (right panel) was determined. Cells were treated with CsA, pyrophenone (Pyr), KT195, or KN93 for 30 min prior to stimulation with H$_2$O$_2$. The results are from 3 independent experiments ± S.E. (*p* < 0.05 when compared with H$_2$O$_2$ stimulated MLFα−/− (*)) or MLFα−/− (**) without inhibitors). b. MLFα−/− were loaded with calcine prior to incubation with inhibitors for 30 min and then stimulated with 1 mM H$_2$O$_2$ for 18 h. The results are from 3 independent experiments ± S.E. (*, *p* < 0.0005 when compared with MLFα−/− without H$_2$O$_2$; **, *p* < 0.005 when compared with H$_2$O$_2$ stimulated MLFα−/− without inhibitors). **DISCUSSION**

This study describes a cell death pathway induced in mouse lung fibroblasts by A23187 with characteristics of primary necrosis involving rapid formation of MPTP due to calcium
overload and plasma membrane rupture resulting in LDH release. There is a direct correlation between the release of LDH and fatty acids, which occurs at a later step after mitochondrial calcium loading and correlates with MPTP formation (Fig. 12). This is supported by data showing that CsA and OAG inhibit fatty acid release without blocking mitochondrial calcium uptake in response to A23187. By directly blocking MPTP formation, CsA and OAG actually enhance levels of mitochondrial calcium. In addition, micromolar concentrations of thapsigargin that directly trigger MPTP formation stimulate fatty acid release that is blocked by CsA. The mechanism involved in the direct induction of MPTP by thapsigargin is not known, but it is not dependent on extramitochondrial calcium and may be due to an increase in mitochondrial Ca\(^{2+}\) released from binding sites in the mitochondrial matrix (61). Our results in intact cells also suggest that thapsigargin induces MPTP independent of extramitochondrial calcium because it occurs when extracellular calcium is chelated with EGTA, and is not blocked by serine hydrolase inhibitors that prevent uptake of cytosolic calcium into the mitochondria.

A comparison of lung fibroblasts from wild type and knockout mice demonstrated that fatty acid release that accompanies MPTP formation is not mediated by cPLA\(_2\)\(\alpha\) or cPLA\(_2\)\(\zeta\). Several studies have strongly implicated iPLA\(_2\)\(\gamma\) (PNPLA8) in regulating calcium-induced MPTP formation based on genetic ablation and use of the iPLA\(_2\)\(\gamma\) enantioselective inhibitor R-bromoenolactone (28, 29, 31). However, we found that racemic bromoenolactone, which inhibits iPLA\(_2\)\(\gamma\) (PNPLA8) and iPLA\(_2\)\(\beta\), did not inhibit A23187-induced MPTP formation or fatty acid release. Arachidonic acid released by cPLA\(_2\)\(\alpha\) has been suggested to mediate cell death and MPTP formation (32, 33). The comparison of A23187-stimulated IMLF\(\alpha^{+/+}\) and IMLF\(\alpha^{-/-}\) showed no role for cPLA\(_2\)\(\alpha\) and no correlation in actual levels of arachidonic acid released with A23187-stimulated cell death. The results using OAG show that despite enhancing cPLA\(_2\)\(\alpha\)-mediated arachidonic acid release in IMLF\(\alpha^{+/+}\), OAG-treated cells are protected from A23187-stimulated cell death. The ability of OAG and CsA to inhibit fatty acid release and necrotic cell death may reflect an important role for site-specific lipid hydrolysis in regulating MPTP formation. Identification of the enzyme responsible for fatty acid release is important for determining how mitochondrial membrane lipid changes regulate MPTP formation.

Our results have uncovered a novel pathway implicating a serine hydrolase in regulating mitochondrial calcium uptake. This is supported by results showing that reduction of the ketone carbonyl in pyrrophenone greatly reduced its ability to block A23187-stimulated cell death. In addition, mitochondrial calcium uptake in permeabilized cells mediated by the MCU, based on RU360 inhibition, is blocked by pyrrophenone. The inhibition by pyrrophenone occurred at concentrations often used (1–2 \(\mu\)M) to “selectively” inhibit cPLA\(_2\)\(\alpha\) complicating its use to investigate the role of cPLA\(_2\)\(\alpha\) in mediating calcium-induced arachidonic acid release. The other small molecule inhibitor that blocked cell death, KT195, is a derivative of 1,2,3-triazole urea that inhibits serine hydrolases by covalent, irreversible carbamoylation of the active site serine nucleophile (37, 65). The triazole ureas show promise for the development of selective serine hydrolase inhibitors (65). Other classes of serine hydrolase inhibitors were ineffective such as methylarachidonoyl fluorophosphonate (data not shown), which broadly targets a large number of serine hydrolases (66).

The serine hydrolase inhibitors block mitochondrial calcium uptake in cells stimulated with A23187 and in permeabilized cells but not in isolated mitochondria. Calcium uptake and MPTP formation (mitochondrial swelling) in isolated mitochondria were blocked by RU360 suggesting they were mediated by the MCU. A serine residue has been identified in the MCU as the site necessary for RU360 inhibition (22). The inability of pyrrophenone and KT195 to block MCU-mediated calcium uptake in isolated mitochondria suggests that they are not directly targeting serine residues in the MCU, and that the regulatory step targeted by the inhibitors is lost in isolated mitochondria.

The serine hydrolase inhibitors also blocked MPTP formation and necrotic cell death induced by \(\text{H}_2\text{O}_2\). Pyrrophenone, KT195, CsA, and KN93 only partially blocked arachidonic acid release and cell death suggesting that other cell death pathways are triggered by \(\text{H}_2\text{O}_2\). The cell death pathway in lung fibroblasts triggered by A23187 and \(\text{H}_2\text{O}_2\) that involves MPTP formation is a regulated process mediated by activation of CaMKII. Pathophysiological stress conditions promote activation of CaMKII leading to mitochondrial calcium overload and MPTP formation (19). CaMKII activation mediates the pathological effects of ischemia/reperfusion injury and promotes cardiovascular diseases (67, 68). A recent report demonstrated a direct role for CaMKII in promoting MPTP formation by phos-
phorylating and increasing the MCU current (20). Developing small molecule cell-permeable inhibitors that block excess calcium uptake have potential for controlling the deleterious affects on the mitochondria and preventing necrotic cell death (22).
