We characterize the importance of metallicity on the presence of molecular hydrogen in damped Lyman-\(\alpha\) (DLA) systems. We construct a representative sample of 18 DLA/sub-DLA systems with \(\log N(\text{H} \alpha) > 19.5\) at high redshift (\(z_{\text{abs}} > 1.8\)) with metallicities relative to solar \([X/\text{H}] > -1.3\) (with \([X/\text{H}] = \log \frac{N(X)}{N(\text{H})} - \log (X/H)_{\odot}\) and \(X\) either Zn, S or Si). We gather data covering the expected wavelength range of redshifted \(\text{H}_2\) absorption lines on all systems in the sample from either the literature (10 DLAs), the UVES-archive or new VLT-UVES observations for four of them. The sample is large enough to discuss for the first time the importance of metallicity as a criterion for the presence of molecular hydrogen in the neutral phase at high-\(z\). From the new observations, we report two new detections of molecular hydrogen in the systems at \(z_{\text{abs}} = 2.431\) toward Q 2343+125 and \(z_{\text{abs}} = 2.426\) toward Q 2348–011. We compare the \(\text{H}_2\) detection fraction in the high-metallicity sample with the detection fraction in the overall sample from Ledoux et al. (2003). We show that the fraction of DLA systems with \(\log f = \log \frac{2N(\text{H}_2)}{2N(\text{H}_2) + N(\text{H} \alpha)} > -4\) is as large as 50% for \([X/\text{H}] > -0.7\) when it is only \(\sim 5\%\) for \([X/\text{H}] < -1.3\) and \(\sim 15\%\) in the overall sample (with \(-2.5 < [X/\text{H}] < -0.3\)). This demonstrates that the presence of molecular hydrogen at high redshift is strongly correlated with metallicity.

Abstract.

1. Introduction

Early searches for molecular hydrogen in DLAs, though not systematic, have lead to either small values of or upper limits on the molecular fraction of the gas. For a long time, only the DLA at $z_{\text{abs}} = 2.811$ toward Q 0528–250 was known to contain H$_2$ molecules (Levshakov & Varshalovich 1985, Foltz et al. 1988). Ge & Bechtold (1999) searched for H$_2$ in a sample of eight DLAs using the MMT moderate-resolution spectrograph (FWHM = 1 Å). Apart from the detection of molecular hydrogen at $z_{\text{abs}} = 1.973$ and 2.338 toward, respectively, Q 0013–004 and Q 1232+082, they measured in the other systems upper limits on $f$ in the range $10^{-6} - 10^{-4}$.

A major step forward in understanding the nature of DLAs through their molecular hydrogen content has recently been made possible by the unique high-resolution and blue-sensitivity capabilities of UVES at the VLT. In the course of the first large and systematic survey for H$_2$ at high redshift, we have searched for H$_2$ in DLAs down to a detection limit of typically $N(\text{H}_2) = 2 \times 10^{14}$ cm$^{-2}$ (Petitjean et al. 2000, Ledoux et al. 2003). Out of the 33 surveyed systems, eight had firm detections of associated H$_2$ absorption lines. Considering that three detections were already known from past searches, H$_2$ was detected in ~15% of the surveyed systems. The existence of a correlation between metallicity and depletion factor, measured as [X/Fe] (with X = Zn, S or Si) was demonstrated (see also Ledoux et al. 2002a) and the DLA and sub-DLA systems where H$_2$ was detected were usually among those having the highest metallicities.

However, the high metallicity end of the Ledoux’s sample was biased by the presence of already known detections. Therefore, to investigate further this possible dependence with metallicity, and derive what is the actual molecular content of the high-redshift gas with highest metallicity, we have searched a representative sample of high metallicity DLAs for H$_2$. The number of H$_2$ measurements in systems with $[\text{X/H}] > -1.3$ is twice larger in our sample compared to previous surveys. We describe the sample and the observations in Section 2, present two new detections of H$_2$ in Section 3 and the results of the survey and our conclusions in Section 4.

2. Sample and Observations

We have selected from the literature all $z > 1.8$ DLAs and sub-DLAs systems (log $N(\text{H}_1) \geq 19.5$) with previously measured elemental abundances (e.g. Prochaska & Wolfe 2001, Kulkarni & Fall 2002) larger than $[\text{X/H}] > -1.3$ and accessible to UVES. The inclusion of sub-DLAs is justified by the fact that for log $N(\text{H}_1) > 19.5$ most of the hydrogen is neutral (Viegas 1995). In addition, Ledoux et al. (2003) have shown that for log $N(\text{H}_1) > 19.5$, there is no correlation between the presence of H$_2$ and the H$_1$ column density. The fact that we include ALL known systems with these criteria guarantees that the sample is representative of the population of DLA-subDLA.

We ended up with a sample of 15 DLAs and 3 sub-DLAs (with log $N(\text{H}_1) = 19.7, 20.10$ and 20.25) presented in Table 1. The H$_2$ content of ten of these systems had already been published (Srianand & Petitjean 2001, Petitjean et al. 2002, Ledoux et al. 2002b, 2003, 2006b, Srianand et al. 2005 and Heinmüller et al. 2006). Five of the eight remaining systems had data in the UVES archive (Q 1209+093: Prog. 67.A-0146 P.I. Vladilo; Q 2116–358: Prog. 65.O-0158 P.I. Pettini; Q 2230+025: Prog. 70.B-0258,
We report two new detections of H$_2$ (Srianand et al. 2000). Ultraviolet and Visible Echelle Spectrograph (UVES, Dekker et al. 2000) mounted on the ESO Kueyen VLT-UT2 8.2 m telescope on Cerro Paranal in Chile. These new observations resulted in two new detections described in the next Section.

The data for each of the eight QSOs were reduced using the UVES pipeline which is available as a context of the ESO MIDAS data reduction system (see e.g. Ledoux et al. 2003 for details). Standard Voigt-profile fitting methods were used for the analysis of metal lines and molecular lines, when detected, to determine column densities using the oscillator strengths compiled in Ledoux et al. (2003) for metal species and the oscillator strengths given by Morton & Dinerstein (1976) for H$_2$. We adopted the Solar abundances from Morton (2003) based on meteoritic data from Grevesse & Sauval (2002).

The characteristics of the sample are summarized in Table 1. The H i column densities and most of metallicities are from the compilation by Ledoux et al. (2006a). Slight differences with previously published values, e.g. Ledoux et al. (2003), are due to the use of different damping coefficients for H i. The only known z > 1.8 H$_2$ bearing DLA system out of this sample is the system at $z_{\text{abs}} = 2.337$ toward Q 1232+082 (Srianand et al. 2000).

3. Two new detections

We report two new detections of H$_2$ in DLAs from our new observations. Details analysis and interpretation of the physical conditions in these two DLAs are out of the scope of the present work and will be described in a subsequent paper.

3.1. Q 2343+125, $z_{\text{abs}} = 2.431$

This DLA system has first been studied by Sargent et al. (1988). High resolution data have been described by Lu et al. (1996), D’Odorico et al. (2002) and Dessauges-Zavadsky et al. (2004). The profile of the metal lines is spread over more than 250 km s$^{-1}$ from $z_{\text{abs}} = 2.4283$ to 2.4313 but the strongest component is centered at $z_{\text{abs}} = 2.43127$ corresponding to the red edge of the above redshift range. From Voigt-profile fitting to the H i Lyman-α, β and γ lines, we find that the dumped Lyman-α line is centered at $z_{\text{abs}} = 2.431$ and the column density is log N(H i) = 20.40 ± 0.07, consistent with previous measurement by D’Odorico et al. (2002); log N(H i) = 20.35 ± 0.05. We use Zn as the reference species for metallicity measurement and find [Zn/H] = −0.89±0.08. This is consistent with previous findings. Absorption from the J = 1 and probably from the J = 0 rotational levels of H$_2$ is detected in this system at $z_{\text{abs}} = 2.43127$ (see Fig. 1). The optically thin H$_2$ absorption lines are very weak, i.e. close to but above the 3σ detection limit. A very careful normalization of the spectrum has been performed, adjusting the continuum while fitting the lines. The best-fitting consistent model for H$_2$ is shown in Fig. 1. The total H$_2$ column density, integrated over the J = 0 and 1 levels, is estimated to be log N(H$_2$) = 13.69 ± 0.09 (12.97±0.04 and 13.60±0.10 for J = 0 and 1 respectively). This leads to the smallest molecular fraction observed up to now, log f = −6.41±0.16. We also derive an upper limit on the detection of absorption from the J = 2 level, log N(H$_2$-J=2) < 13.1 at the 3σ level.

3.2. Q 2348−011, $z_{\text{abs}} = 2.426$

There are two DLA systems at $z_{\text{abs}} = 2.426$ and $z_{\text{abs}} = 2.615$ toward Q 2348−011, with total neutral hydrogen column densities of respectively log N(H i) = 20.50 ± 0.10 and log N(H i) = 21.30 ± 0.08. Conspicuous H$_2$ absorptions are detected in the $z_{\text{abs}} = 2.426$ DLA system, the only system to be considered here as displaying a high metallicity (see Fig. 2). The molecular lines are very numerous and strong but the spectral resolution of our data is high enough to allow unambiguous detection and accurate determination of the line parameters. Seven H$_2$ components spread over about 300 km s$^{-1}$ were used for the H$_2$ fit. It is interesting to note that the strongest metal component (at $V = 0$ km s$^{-1}$ in Fig. 2) has no associated H$_2$ absorption. Strong H$_2$ absorption is seen at $V ≃ −150$ and +50 km s$^{-1}$. All seven molecular components have associated C i absorption. However, additional components are needed to fit the metal absorption lines: 9 components for C i and 13 com-

1 Neutral hydrogen column densities and metallicities relative to Solar, $[\text{X}/\text{H}] = \log [\text{N}(\text{X})/\text{N}(\text{H})] − \log [\text{N}(\text{X})/\text{N}(\text{H})]_\odot$ (with X = Zn as the reference element when Zn ii is detected, or else either S or Si) are from Ledoux et al. (2006a).
2 Molecular hydrogen column densities are summed up over all J levels in case of detection and upper limits for $J = 0$ and $J = 1$ are given in case of non-detection.
3 Molecular fraction, $f = 2N(\text{H}_2)/(2N(\text{H}_2) + N(\text{H}_1))$.

4. Metallicity as a criterion for the presence of molecular hydrogen

From Table 1, it can be seen that H$_2$ is detected in nine high-metallicity systems out of 18. However, for two of the detections, the corresponding value of log $f$ is smaller than most of the upper limits derived for other systems. All upper limits are smaller than −4.5 and all detections larger than these upper limits are larger than −3. We therefore define a system with large (respectively small) H$_2$ content if log $f$ is larger (respectively smaller) than −4.

In Fig. 3 we plot the molecular fraction, log $f$, versus metallicity, [X/H], for our representative sample of DLAs with [X/H] > −1.3 (18 measurements summarized in Table 1) and measurements by Ledoux et al. (2003) for [X/H] < −1.3 (23 measurements). The log $f$ distribution is bimodal with an apparent gap in the range −5 < log $f$ < −3.5 justifying the above classification of systems. Note that this jump in log $f$ has already been noticed before by Ledoux et al. (2003) and is similar to what is seen in our Galaxy (Savage et al. 1977; see also Srianand et al. 2005). It is apparent that the fraction of systems with molecular fraction log $f > −4$ increases with increasing metallicity. It is only ∼5% for [X/H] < −1.3 when it is ∼39% for [X/H] > −1.3. This fraction is even larger, 50%, for [X/H] > −0.7 which is the median metallicity for systems with [X/H] > −1.3. In addition, all systems with [X/H] < −1.5 have log $f < −4.5$.

We conclude that metallicity is an important criterion for the presence of molecular hydrogen in DLAs. This may not
be surprizing as the correlation between metallicity and deple-
tion of metals onto dust grains (Ledoux et al. 2003) implies 
that larger metallicity means larger dust content and therefore 
larger H$_2$ formation rate. In addition, the presence of dust im-
plies a larger absorption of UV photons that usually dissoci-
ate the molecule. More generally, Ledoux et al. (2006a) have 
shown that a correlation exists between metallicity and veloc-
ity width in DLAs. If the latter kinematic parameter is inter-
preted as reflecting the mass of the DM halo associated with 
the absorbing object, then DLAs with higher metallicity are 
associated with objects of larger mass in which star formation 
could be enhanced. All this makes it arguable that, in DLAs, 
star-formation activity is probably correlated with the molecu-
lar fraction (Hirashita & Ferrara 2005). It is therefore of first 
importance to survey a large number of DLA systems to de-
fine better their molecular content and use this information 
to derive the physical properties of the gas and the amount of star-
formation occurring in the associated objects.
