The European Sector of the Arctic Ocean is characterized by low CO$_2$ concentrations in seawater during spring and summer, largely due to strong biological uptake driven by extensive plankton blooms in spring. The spring plankton bloom is eventually terminated by nutrient depletion and grazing. However, low CO$_2$ concentrations in seawater and low atmospheric resupply of CO$_2$ can cause episodes during which the phytoplankton growth is limited by CO$_2$. Here, we show that gross primary production (GPP) of Arctic plankton communities increases from 32 to 72% on average with CO$_2$ additions in spring. Enhanced GPP with CO$_2$ additions occur during episodes of high productivity, low CO$_2$ concentration and in the presence of dissolved inorganic nutrients. However, during summer the addition of CO$_2$ suppresses planktonic Arctic GPP. Events of CO$_2$ limitation in spring may contribute to the termination of the Arctic spring plankton blooms. The stimulation of GPP by CO$_2$ during the spring bloom provides a biotic feedback loop that might influence the global role played by the Arctic Ocean as a CO$_2$ sink in the future.

**Keywords:** CO$_2$ limitation, gross primary production, Arctic Ocean, spring blooms, plankton communities, CO$_2$ additions

**INTRODUCTION**

The shelf seas and the shelf edge of the European Arctic Sector are characterized by strong spring plankton blooms that extend between 70 and 80°N in the Barents Sea and the northern Svalbard shelf (Wassmann and Reigstad, 2011). These blooms support high net community production (NCP) rates and fuel the Arctic food web (Vaquer-Sunyer et al., 2013). The strength of the spring Arctic plankton bloom results not only from high primary productivity, but also from a very low respiratory demand of the planktonic community at that time, which leads to high NCP (Vaquer-Sunyer et al., 2013). The spring bloom is associated with increased photoperiod, and depends on light availability, ice cover, water masses and nutrient availability, which lead to extremely pronounced seasonality and spatial heterogeneity (Vaquer-Sunyer et al., 2013). The high biological CO$_2$ uptake in shallow stratified layers during the spring bloom results in rapid CO$_2$ drawdown in the surface waters of the Arctic Ocean (Chierici et al., 2011; Yasunaka et al., 2016). Values as low as 100 µatm of partial pressure of CO$_2$ (pCO$_2$) have been recorded at the end of the spring bloom (Fransson et al., 2009), which is among the lowest pCO$_2$ values reported across the open ocean (Takahashi et al., 2009). As a consequence, several regions of the Arctic Ocean such as the Eurasian shelves and the Barents Sea (Fransson et al., 2001, 2009) and the Bering-Chukchi shelves...
Arctic spring plankton blooms are generally triggered by increased solar radiation with increased photoperiod, and the associated increase in temperature, melting ice and the consequent increase in underwater irradiance and water column stratification (Sakshaug and Skjoldal, 1989; Niebauer, 1991; Reigstad et al., 2002; Hodal et al., 2012; Juul-Pedersen et al., 2015). The spring bloom is usually considered to be terminated by nutrient depletion and grazing, but secondary blooms can be produced by wind-driven events that break down the weak stratification and supply nutrients to the euphotic zone (Sakshaug and Skjoldal, 1989; Niebauer, 1991; Wassmann et al., 1999; Tremblay et al., 2006; Fransson et al., 2017). However, experimental assessments suggest that low CO\textsubscript{2} concentrations can limit primary production (Mercado and Gordillo, 2011), such as the low CO\textsubscript{2} concentrations observed during spring and summer in the Arctic Ocean (Bates and Mathis, 2009).

Limitation by CO\textsubscript{2} in planktonic communities has indeed been experimentally observed in the European Arctic sector (Engel et al., 2013; Holding et al., 2015) and in sub-ice blooms in the Baltic Sea (Spilling, 2007) as well as in temperate regions of the Atlantic Ocean (Hein and Sand-Jensen, 1997). However, Arctic CO\textsubscript{2} limitation seems to be temperature-dependent (Holding et al., 2015), light-dependent and acclimation of subarctic plankton productivity to high levels of CO\textsubscript{2} has been observed (Hoppe et al., 2017). When CO\textsubscript{2} is depleted, the intracellular CO\textsubscript{2} concentration decreases, leading to a lower diffusive CO\textsubscript{2} supply that reduces photosynthetic rates (Riebesell et al., 1993) and results in CO\textsubscript{2}-limited phytoplankton production (Rost et al., 2006). In polar regions, CO\textsubscript{2} limitation is more likely than in temperate regions because the conversion of HCO\textsubscript{3} to CO\textsubscript{2} in cold waters with high pH supplies little CO\textsubscript{2}, <5% of the required CO\textsubscript{2} for one polar diatom species (Riebesell et al., 1993). Isotopic evidence also points at CO\textsubscript{2} limitation during peak and late bloom phases in the Arctic Ocean, reflected in heavier δ\textsuperscript{13}C signatures in plankton (Tamelander et al., 2009). However, experimental and observational evidence of CO\textsubscript{2} limitation of phytoplankton production during the spring phytoplankton bloom is limited, so whether this is an episodic or chronic situation remains unclear.

Here, we test the hypothesis that the characteristically low CO\textsubscript{2} concentrations in seawater during the Arctic spring and early summer limit the primary productivity of planktonic communities before dissolved inorganic nutrients are fully consumed. To test this hypothesis, we conducted a series of seven experiments to test the response of planktonic gross primary production (GPP) to elevated CO\textsubscript{2}. These communities were sampled west and northwest of Svalbard (European Arctic sector), during spring and summer. The locations of the experiments were heterogeneous (Figure S1); four of the experiments were located in the path of the West Spitsbergen Current (WSC), that flows northward along the shelf edge at the west of the Svalbard Islands, and two of the experiments were located in the mouths of two western fjords. We sampled seven subsurface planktonic communities in the spring and summer of 2014 and 2015, thereby experiencing a wide range of conditions in terms of community metabolism and biogeochemical conditions. We evaluated the net biological demand for CO\textsubscript{2}, as the NCP in the euphotic layer, compared this to the atmospheric supply of CO\textsubscript{2} through air-sea exchange, and assessed the experimental response of the GPP of the plankton communities sampled to elevated CO\textsubscript{2}.

**MATERIALS AND METHODS**

Three cruises were conducted to the west and northwest of the Svalbard shelf where seven experiments on CO\textsubscript{2} addition were carried out on board R/V Helmer Hanssen in 2014 and 2015: two experiments were run in May, three in August 2014 and two in May 2015 (Figure S1). Results of the first experiment, in May 2014, were previously Holding et al. (2015).

A 50 L sample of subsurface seawater (3 m) was collected using a Rosette sampler system, which was fitted with Niskin bottles and a calibrated CTD profiler (Seabird 911plus), and located in two 25 L closed tanks using silicon tubes. Samples to measure the carbonate system parameters, chlorophyll a concentration (Chl a), nutrients concentrations and phytoplankton community composition were taken and preserved for further analysis.

To simulate the predicted scenario of atmospheric pCO\textsubscript{2} by 2,100 (IPCC Panel, 2014), 25 L of seawater was stored in a closed tank and the remaining 25 L were bubbled with CO\textsubscript{2} until ~1,000 ppm pCO\textsubscript{2} was reached, using an Environmental Gas Monitor (EGM-3) to measure pCO\textsubscript{2} while a water pump ensured proper mixing. The treated and untreated water were gently mixed in 10 L carboys to produce an intermediate level and a gradient of increasing pCO\textsubscript{2} between treatments. In 2014, this gradient included four pCO\textsubscript{2} levels in the experiments, but the experimental design was simplified, based on the results obtained, to have only two elevated pCO\textsubscript{2} levels in 2015. This allowed experiments with a greater number of communities to be conducted within the time available (see pCO\textsubscript{2} of each treatment in Table S1).

After every treatment reached the targeted pCO\textsubscript{2} (45 min), two sets of samples were collected. The first set was immediately preserved to determine the initial dissolved O\textsubscript{2} concentration, δ\textsuperscript{18}O (in dissolved O\textsubscript{2}), total alkalinity (TA) and total dissolved inorganic carbon (DIC). The second set of samples was incubated for 24 h and subsequently preserved to determine the same parameters at the end of the incubation. In 2014 the second set of samples was incubated in transparent methacrylate tubes which allowed the 60% transmittance of photosynthetically active radiation surface (PAR) to simulate the irradiance at 3 m depth, with flow-through surface seawater baths to maintain samples close to the in-situ temperature during the cruises of 2014. In May 2015, samples were incubated in a 40-L tank with circulation of surface seawater and neutral screens allowed the 80% transmittance of surface PAR.

Gross primary production (GPP) was measured from the photosynthetic production of δ\textsuperscript{18}O\textsubscript{2} following the addition of H\textsubscript{2}\textsuperscript{18}O during a 24 h incubation, according to Bender et al. (1987) and Grande (1988). Four 12-ml vials per treatment, made of...
borosilicate, were immediately fixed with 100 µl of saturated HgCl₂ solution and stored in darkness for further δ¹⁸O_initial analysis. Four other vials per treatment containing glass beads to mix, were labeled with 80 µl of 98% H²¹⁸O, shaken to ensure mixing, incubated for 24 h on deck and subsequently fixed with 100 µl of saturated HgCl₂ solution for further analysis. At the Stable-Isotope Laboratory of the Instituto Andaluz de Ciencias de la Tierra (IACT-CSIC) Stable-Isotope Laboratory, a 4 ml headspace of Helium was generated in each vial. Vials were left to equilibrate for 24 h at room temperature letting the dissolved gases in water equilibrate with the headspace, originally Helium 100%. After 24 h, the δ¹⁸O of dissolved oxygen in the headspace was measured in a Finnigan DeltaPlus XP isotope ratio mass spectrometer, with precision better than 0.1‰. The flow was passed through a liquid nitrogen trap to remove water vapor before entering GasBench II. Oxygen and nitrogen were separated in a Molecular Sieve 5Å chromatographic column. Data, which were corrected with atmospheric air, are reported as δ¹⁸O value (‰) relative to V-SMOW (Vienna Standard Mean Ocean Water) standard.

The δ¹⁸O(H₂O) composition of labeled samples was measured 3 weeks later in a liquid water isotope analyzer (Los Gatos Research) with precision of 0.2‰. In order to avoid contamination of the analyzer with highly δ¹⁸O-enriched H₂O (≈3,000‰), the labeled water was diluted (approximately 1:20) with a laboratory standard of known isotopic composition. GPP was calculated from Bender et al. (1999) as:

\[
GPP = \left(\frac{\delta_{\text{O}}^{18}\text{O}_{\text{final}} - \delta_{\text{O}}^{18}\text{O}_{\text{initial}}}{\delta_{\text{O}}^{18}\text{O}_{\text{water}} - \delta_{\text{O}}^{18}\text{O}_{\text{initial}}}\right) \times [O_2]_{\text{initial}}
\]

where δ¹⁸O_initial and δ¹⁸O_final are the initial and final δ¹⁸O of dissolved O₂ (%o vs. V-SMOW), respectively, δ¹⁸O_water is the δ¹⁸O of the labeled seawater (%o vs. V-SMOW) and [O₂]_initial is the initial O₂ concentration (µmol O₂ L⁻¹) measured by high-precision Winkler titration.

In addition to the δ¹⁸O method, the O₂ mass balance method (Carpenter, 1965; Carritt and Carpenter, 1966) was used to estimate the NCP and the community respiration (R) in darkness in the water column of the CO₂ experiments stations, as well as in 5 additional stations in the nearby area. NCP and R rates were calculated by subtracting initial dissolved oxygen concentrations from dissolved oxygen concentrations measured after incubation in the dark and light conditions, respectively. GPP measured with the O₂ mass balance method (GPP-O₂) was calculated by solving the mass balance equation GPP-O₂ = NCP + R (Carpenter, 1965; Carritt and Carpenter, 1966). NCP and R was determined at 3 different depths on the euphotic layer (3 m, 15 m and 25 m, on average). Seawater samples were collected with a Rosette sampler system fitted with 10-L Niskin bottles and a calibrated CTD (Seabird 911plus). Seawater was carefully siphoned from the Niskin bottles into 100 ml narrow-mouth, borosilicate Winkler bottles. Seven replicates were used to determine the initial oxygen concentration, and seven replicates were incubated for 24 h in dark and in light. The bottles were incubated on deck, following the same procedure previously mentioned for GPP samples measured with the δ¹⁸O method. Light attenuation inside each methacrylate incubator was estimated with a Photosynthetically Available Radiation (PAR) radiometer (Biospherical Instruments Inc. QSL-101). Light attenuation was simulated using screens as a % of the on-deck PAR with 0 screen, 2 screens, 3 screens, simulating 60, 33, and 25% of surface PAR, respectively. GPP-O₂ was calculated by the difference between the mean final oxygen concentration of light incubated bottles and the mean final oxygen concentration of dark incubated bottles. Oxygen concentrations were determined by automated high-precision Winkler titration (Carpenter, 1965; Carritt and Carpenter, 1966), using a potentiometric electrode and automated endpoint detection (Oudot et al., 1988). Values that reported O₂ production in darkness were considered unviable and were discarded from the database. The communities were then characterized as autotrophic communities (GPP/R ratios > 1, NCP > 0) or heterotrophic (GPP/R ratios < 1, NCP < 0).

Sampling and analyses for the determination of the carbonate chemistry in the experiments followed the standard operating procedures from Dickson et al. (2007). Seawater for TA and DIC analyses were collected from each treatment carboy with a silicon tube and carefully siphoned in two 250 ml borosilicate bottles per treatment. Initial samples were preserved with 60 µL of mercury chloride and stored in dark and cold until analysis onboard and the final samples were preserved after 24 h of incubation and analyzed onboard. TA was determined using potentiometric titration in open cell with 0.05 mol L⁻¹ hydrochloric acid using a Titrino system (Metrohm, Switzerland). The precision was ±2 µmol kg⁻¹, obtained by triplicate analysis of one sample on a daily basis and Certified Reference Material provided by Dr. Andrew Dickson (Scripps Institution of Oceanography, University of California) was used for accuracy check of the TA analyses. pH was determined spectrophotometrically, using m-cresol purple and a diode-array spectrophotometer, HP8453 (Clayton and Byrne, 1993). The analytical precision was estimated to ±0.002 pH units, which was determined by triplicate analysis of one sample every day. The pH of the indicator solution was measured daily using a 0.2-mm flow cell, this was then used as correction for the perturbation caused by the addition of the indicator solution (Chierici et al., 1999).

The CO₂ concentration was calculated from TA and DIC analysis using the program CO2SYS (Pierrot et al., 2006) and output parameters were standardized to standard pressure and in situ water temperature. We used the carbonate dissociation constants (K₁ and K₂) of Mehrbach et al. (1973) as refitted by Dickson and Millero (1987), and the KSO₄ determined by Dickson (1990). The CO₂ removal rates were calculated from the difference in CO₂ concentration during 24 h incubation.

The air-sea CO₂ flux (F) was calculated using the measured fCO₂ according to the gas flux formulation:

\[
F = K_0 \times k \times (fCO₂ - fCO₂ \text{air})
\]

\[
k = 0.31 \times u^2 \times (Sc/660) - 0.5
\]

Where K₀ is the solubility, k is the transfer velocity for air-sea CO₂ exchange, fCO₂ air, and fCO₂ are the atmospheric and sea surface fCO₂, respectively, u is the wind speed (mean daily) and Sc is the Schmidt number. The solubility (K₀) was calculated according to Weiss (1974) using the measured sea surface
temperature (SST) and salinity values. The transfer velocities (k) and the Schmidt number (Sc) were calculated according to Wanninkhof (1992) for monthly and daily average observed wind speed (Equation 3) and are based on wind speed (u). The $f_{CO_2}^{air}$ was estimated from the monthly $x_{CO_2}^{sea}$ from Ny-Ålesund (www.nilu.no). The dry atmospheric mole fraction was converted into the atmospheric p$CO_2$ (p$CO_2^{sea}$) in wet air using the relative air humidity, air pressure and air temperature for the date when the fluxes based on ship data were estimated.

Chlorophyll a concentration (Chl a) was collected from the same depth at which seawater was collected for the experiments conducted in May 2015 and was determined fluorometrically by filtering 200 mL of the sub-surface seawater sampled through Whatman GF/F filters and extracted in 90% acetone for 24 h before spectrofluorometric determination using a Shimadzu RF-5301PC spectrophotometer, following Parsons et al. (1984). For the experiments conducted in May and August 2014, Chl a was derived from the fluorescence measured in a calibrated CTD (Seabird 911plus) at the depth of the sampled seawater using linear regression equations between results of Chl a and fluorescence measured in from previous vertical profiles in same stations ($R^2 > 0.67$ and $n = 12$ for every regression equation).

Samples of unfiltered 50 mL seawater was collected at the same depth of the experiments conducted in May 2015 for analysis of phosphorus, nitrate-nitrite, and silicate concentrations and vials were kept frozen until analysis using standard seawater methods using a Flow Solution IV analyzer from O.I. Analytical, USA. The analyzer was calibrated using reference seawater from Ocean Scientific International Ltd. UK. Nutrients concentrations of the experiments conducted in May and August 2014 were analyzed in a previous vertical profile from the same station.

Samples of 100 mL of untreated plankton community were collected from each experimental community, at the onset of the experiment, and fixed with glutaraldehyde (at 1–1.5%). Cells were counted following the Utermöhl method, while also measuring the linear dimensions of the different taxa present to allow biovolume calculations by approximation to the nearest geometrical figure. Samples were concentrated in 50-ml chambers for 48 h and counted in a transmitted-light inverted microscope (Zeiss Axiosvert 200) at 200x or 400x magnification depending on cell size. Phytoplankton cells were differentiated into species or genus, and their contribution to the communities is presented as % of the community biovolume.

The response of GPP to increased CO$_2$ was compared among experiments using the Ln-transformed effect size:

$$\text{Ln effect size GPP} = \text{LnGPP}_E - \text{LnGPP}_C$$

Where GPP$_E$ and GPP$_C$ are the mean response in the experimental and control treatments, respectively ($n = 3–4$). The effect size is frequently used in experimental ecology to quantify the proportional effect of a treatment and to facilitate the comparison of biological responses across experiments (Hedges et al., 1999). An Ln effect size of GPP of zero is interpreted as having no effect on GPP, whereas a positive value indicates a positive effect of CO$_2$ on GPP and a negative value indicates a negative effect of CO$_2$ on GPP. The variance in the Ln effect size was calculated following Kroeker et al. (2010). Moreover, comparisons based on the Ln effect size GPP did not assume normality and were heterogeneous because the experiments encompassed distinct phases of blooms, which occur rapidly and yield extreme data (i.e., very low p$CO_2$ and high GPP; R Core Team, 2014). The analyses were carried out using RStudio 0.98.945 and the “Metafor package” designed for meta-analyses (Viechtbauer, 2010).

**RESULTS**

**Community Metabolism and CO$_2$ Demand**

GPP- O$_2$ within the euphotic layer increased with increasing Chl a concentration ($p < 0.0001$, $R^2 = 0.81$, Figure S2), resulting in low-CO$_2$ waters (ranging from 281 to 128 $\mu$atm of p$CO_2$, Table 1). GPP, measured with the $^{18}$O method, of these low-CO$_2$ communities ranged from 5.8 to 82.4 $\mu$mol O$_2$ L$^{-1}$ d$^{-1}$ in spring, under blooming conditions, while in summer GPP was much lower (0.4–1.4 $\mu$mol O$_2$ L$^{-1}$ d$^{-1}$), reflecting a recycling phase. The GPP- O$_2$/R ratio was extremely high in the euphotic layer in spring (43.4 $\pm$ 0.85, with a maximum value of 244.6) compared with low values in summer (2.67 $\pm$ 0.73). As a result, the waters sampled were consistently undersaturated in CO$_2$ and with a broad range of primary productivity rates. Consistent with the role of biota as a CO$_2$ sink, there was oceanic uptake of atmospheric CO$_2$ at the stations sampled, which increased with increasing NCP in the euphotic layer (Figure 1, Table 1). However, the resulting input of atmospheric CO$_2$ was much smaller than the net CO$_2$ demand by the plankton community, calculated assuming a 1:1 ratio between O$_2$ and CO$_2$, accounting for 19%, on average, of the net biological removal (Figure 1, Table 1).

**Response to Experimental CO$_2$ Additions**

*In situ* p$CO_2$ ranged from 128 to 281 $\mu$atm (Table 1, Table S1), within reported *in situ* p$CO_2$ across the Arctic Ocean (78 to 765 $\mu$atm; Bakker et al., 2016), and the experimentally-elevated p$CO_2$ ranged from 178 to 1,096 $\mu$atm (Table S1), consistent with predicted scenarios of atmospheric CO$_2$ by 2,100 (IPCC, 2014). The experimentally tested plankton communities represented variable biogeochemical parameters, from low-productivity communities supported by nutrient recycling sampled in August 2014, to pre-bloom, blooming and decay phases, sampled in May 2014 and 2015. All of the waters sampled were characterized by low salinity ($<34.3$) and low temperatures ($<0.1^\circ$C), except in August 2014-1 ($7^\circ$C), probably due to the proximity of surface waters to the WSC that transports warm Atlantic water mass.

Three of the experiments showed positive responses to CO$_2$ additions, all of them for communities sampled in May (May 2014-1, May 2015-1, May 2015-2). These were characterized by the highest *in situ* GPP (6.2, 46, and 82.4 $\mu$mol O$_2$ L$^{-1}$ d$^{-1}$, respectively), high Chl a concentration (7.9, 10.6, and 13 $\mu$g Chl a L$^{-1}$), low p$CO_2$ ($<193$ $\mu$atm) and either low nutrient...

Na indicates not available and the phytoplankton abundance is reported as the % of the microphytoplankton biovolume.
concentrations (0.7 μmol N L$^{-1}$, 0.1 μmol P L$^{-1}$, and 0.9 μmol Si L$^{-1}$, in May 2014-1), depleted in nitrite and nitrate (0 NO$_3$ + NO$_2$, 0.1 PO$_4$, 0.4 SiO$_4$, in May 2015-1) or slightly higher nitrate, phosphate and silicate (1.7 NO$_3$ + NO$_2$, 0.3 PO$_4$, 1.5 SiO$_4$, in May 2015-2) (Table 1). In these three experiments the phytoplankton communities supported high cell density, with a dominance of diatoms in May 2015-1 and 2, such as the centric diatoms Thalassiosira sp. and Chaetoceros sp., and a community dominated by Phaeocystis sp. in May 2014-1 (Table 1). The GPP yield per μmol of added CO$_2$ of every community tested was calculated as the slope of the fitted regression equations between GPP and the concentration of added CO$_2$ (Table S1, Figure 2). The GPP yield per μmol added CO$_2$ increased with increased GPP at in situ CO$_2$ concentration, being 10-fold higher in spring than in summer (Figure 2).

The response of GPP to CO$_2$ addition was negative in four of the seven experiments, including all of the experiments conducted in August and one experiment in May 2014 (2014-2, Table 1), with communities generally characterized by low GPP (from 5.8 to 0.4 μmol O$_2$ L$^{-1}$ d$^{-1}$), low Chl $a$ concentration (1.8 to 0.3 μg L$^{-1}$), low pCO$_2$ (ranging from 128 to 281 μatm) and low abundance of phytoplankton, dominated by diatoms such as Chaetoceros sp. and a presence of dinoflagellates, such as Protoperidinium sp. (Table 1). Dissolved inorganic nutrients concentrations were generally low (nitrite and nitrate ∼0.7 μmol N L$^{-1}$, phosphate ∼0.1 μmol P L$^{-1}$, and silicate ∼0.6 μmol Si L$^{-1}$), except for the experiment conducted in August 2014 (2014-1), which showed high nitrate (10.3 μmol N L$^{-1}$) and silicate concentrations (4.8 μmol Si L$^{-1}$), despite low in situ GPP (1.4 μmol O$_2$ L$^{-1}$ d$^{-1}$).

A meta-analysis of the experimental results revealed consistent patterns in the responses observed. In particular, the response to CO$_2$ enrichment, measured as the Ln effect size for GPP, increased significantly with the biomass of the communities tested ($p = 0.002, R^2 = 0.36$, Figure 3A). The Ln effect size of GPP became positive, indicative of an increase in GPP under elevated CO$_2$, during dense blooms with Chl $a$ concentrations in excess of 7 μg Chl $a$ L$^{-1}$ (Figure 3A). The Ln effect size for GPP declined with increasing in situ pCO$_2$ and became positive when the in situ pCO$_2$ was below 150 μatm (Figure 3B). The strongest GPP stimulation was found in a community with intermediate GPP (6.2 ± 0.1 μmol O$_2$ L$^{-1}$ d$^{-1}$, experiment May 2014-1) and dominated by Phaeocystis sp. (99.4% of the biovolume, Table 1, Table S1, Figure 4). Two diatom-dominated communities (51.5% and 76.6% of the microphytoplankton biovolume) with high GPP (46 ± 6 and 82.4 ± 11.4 μmol O$_2$ L$^{-1}$ d$^{-1}$) were also stimulated by CO$_2$ enrichment (May 2015-1 and May 2015-2 respectively, Table 1, Table S1). As a result of the CO$_2$ unsaturated waters and the low atmospheric CO$_2$ input (Figure 1), the turnover of CO$_2$ pool in the communities tested, calculated as the slopes of fitted regression equations between the CO$_2$ removal rates (in units of μmol CO$_2$ L$^{-1}$ d$^{-1}$) and the concentration of added CO$_2$, increased with increasing in situ GPP (Figure 5, Table S1).

**DISCUSSION**

The atmospheric resupply of CO$_2$ was far too slow to compensate for the observed biological drawdown of CO$_2$ (19% of removal, Figure 1), resulting in low-CO$_2$ waters at the end of the Arctic spring bloom (Kaltin et al., 2002; Bates et al., 2006; Bates and

---

**FIGURE 1** | Oceanic uptake of CO$_2$ shown by the relationship between the Ln-transformed air-sea CO$_2$ flux and the Ln-transformed NCP integrated in the water column from 3 to 25 m and the regression equation [Ln air-sea flux = 0.35 (±0.1) + 5.95 (±1.1); $p = 0.01, R^2 = 0.64, df = 6$]. The shaded area represents the confidence interval (CI).

Mathis, 2009; Fransson et al., 2009, 2017). Upward CO₂ supply from deeper layers was also likely to be low because the seasonal stratification produced by melting sea ice in the same area leads to small upward diffusive fluxes (Randelhoff et al., 2016). The large imbalances that we observed between net biological CO₂ consumption and supply explain the sensitivity of the Arctic phytoplankton community to CO₂ limitation. The time for photosynthetic removal of the CO₂ pool, in the absence of recycling mechanisms, ranged from more than 10 days for the least productive communities to 3 days for communities in the most active phase of the spring bloom (Figure 5). Respiratory remineralization of CO₂ was characteristically low during the spring bloom (40-fold lower than photosynthetic uptake, i.e., $P/R = 43$) as is the atmospheric input of CO₂, leading to CO₂ depletion, thereby creating the conditions for CO₂ limitation.

**FIGURE 5** The relationship between CO₂ turnover (± SE) and GPP at in situ pCO₂ and the regression equation [CO₂ turnover = 0.10 (±0.02) + 0.003 (±0.0005) GPP in situ; $R^2 = 0.87$, p-value = 0.001], the shaded area indicates the 95% confidence interval (CI) of the regression equation. The shape corresponds with the communities tested in spring (circles) and summer (triangles).
during the spring bloom. The peak of the spring Arctic bloom was characterized by autotrophic communities with high net biological CO$_2$ demand and high P/R ratios on average (43 ± 0.8) showed consistent with previous reports (Vaqueer-Sunyer et al., 2013), with the communities acting as strong CO$_2$ sinks during spring. In August, when recycling processes drive primary production, the average GPP-O$_2$/R ratio (3 ± 0.7) was more than 10-fold lower than that in spring.

The plankton communities tested spanned a range of bloom stages according to the season and the location and yielded a broad diversity of responses to increased CO$_2$, from increased GPP, generally observed (3 of 4 experiments) in the spring, along with a very high GPP yield per unit CO$_2$ added, to suppression of GPP in the summer experiments. This is consistent with expectations, as high net biological demand for CO$_2$ in spring, along with low resupply from low respiration rates and air-sea exchange, lead to a rapid CO$_2$ depletion. In contrast, a closer balance between community production and respiration during the recycling mode, in summer, when communities are strongly nutrient-limited, relieves them from CO$_2$ limitation. The finding of a prevalence of suppression of GPP with CO$_2$ enrichment in the summer was unexpected, as we expected no effect but not a negative one, which we are unable to explain and may in fact reflect pH-dependent processes, as CO$_2$ enrichment leads to decrease in pH, rather than negative effects of CO$_2$ itself.

The broad diversity of responses observed further allowed us, through a meta-analysis approach, to explore the conditions associated with CO$_2$ limitation. In particular, we found that these divergent results were dependent on the biological demand for CO$_2$ and the extent of CO$_2$ depletion in the water column. These findings point at a shifting role of CO$_2$ with seasons, supporting the hypothesis of the existence of transient time windows of CO$_2$ limitation during highly productive periods in spring.

We observed the most negative effect size (i.e., suppression of GPP with addition of CO$_2$) in a community sampled in warm surface water and slightly influenced by melting sea ice (with 7°C temperature and 34.3 salinity), likely indicating an influence of the WSC, transporting warm Atlantic water mass. This community supported low Chl a concentration and the highest pCO$_2$ (281 µatm) observed in this study (Figures 3A,B). This negative result is consistent with the temperature-dependence of the response of GPP to CO$_2$ reported by Holding et al. (2015), as well as with the temperature threshold of 5°C at which Arctic plankton communities have been shown to shift from autotrophic to heterotrophic (Holding et al., 2013). However, the mechanism through which added CO$_2$ suppresses GPP is unclear. It may involve indirect effects of changes in pH on cellular composition (Taraldsvik and Myklestad, 2000) or the pH-dependence of the availability of other nutrients, such as trace metals (Saito and Goepfert, 2008; Shi et al., 2010; Xu et al., 2010, 2012). No or little response to CO$_2$ enrichment was expected in waters with pCO$_2$ near atmospheric equilibrium (Mercado and Gordillo, 2011). In turn, an increase in GPP with CO$_2$ enrichment was expected in cold waters depleted in CO$_2$ relative to atmospheric equilibrium but still containing enough dissolved inorganic nutrients to support primary production (Holding et al., 2015).

Our results showed that GPP increased by 32–72% (Table S1) on average when CO$_2$ was supplied to blooming phytoplankton communities (Chl a > 7 µg L$^{-1}$) supporting high CO$_2$ demand (GPP > 6 µmol O$_2$ L$^{-1}$ d$^{-1}$), and growing under low pCO$_2$ (<150 µatm) and in the presence of low, but inorganic nutrients concentrations. These conditions, found during the Arctic spring bloom, therefore, define those under which episodes episodic CO$_2$ limitation is expected. It was previously found that the CO$_2$ concentration limits photosynthesis of phytoplankton bloom episodes in semi-enclosed systems (Mercado and Gordillo, 2011), but the environmental conditions for CO$_2$ limitation in Arctic communities have not yet been defined. Moreover, previous experimental results showed that increased CO$_2$ concentrations may increase primary production in nutrient-poor communities (Hein and Sand-Jensen, 1997) and during nutrient-depleted conditions resulting in “carbon-overconsumption” (Taucher et al., 2015). Such carbon-overconsumption has been observed (Sambrotto et al., 1993; Banse, 1994) and has been associated with experimental nutrient stress (Taucher et al., 2012, 2015), suggesting that episodes of CO$_2$ limitation could extend into the later phases of a bloom.

Enhanced GPP in response to elevated CO$_2$ was observed in highly productive communities, one dominated by Phaeocystis sp. and two communities dominated by diatoms (Figure 4). However, the strongest enhancement was observed in the community dominated by Phaeocystis sp. (Table 1, Table S1), which is an important Arctic haptophyte that tends to be dominant close to drifting ice (Wassmann et al., 1999), and with increasing salinity and temperature following ice melt events (Lasternas and Agustí, 2010). Phaeocystis sp. is considered to have less-efficient carbon concentration mechanisms (CCMs) than diatoms do (Rost et al., 2008). Elevated CO$_2$ produces a decrease in inorganic carbon affinity and leads to strong downregulation in the expression of CCMs in some eukaryotic algae, such that the diffusive entry of CO$_2$ can be facilitated (Giordano et al., 2005; Reinfelder, 2010; Raven et al., 2011). This suggests a possible mechanism through which the GPP of Phaeocystis sp. and diatom communities are stimulated during CO$_2$-enriched conditions. Besides, the abundance of Phaeocystis sp. was greatest when pCO$_2$ concentrations were lower than 150 µatm, which can potentially influence competitions among phytoplankton species (Tortell et al., 2002), a possibility that was not evaluated in our study. Phaeocystis sp. replaces diatoms when the growth of diatoms is limited by the availability of silicic acid while other nutrients remain available to support growth of non-diatom taxa (Lasternas and Agustí, 2010). Recently, an under ice bloom in the Arctic dominated by Phaeocystis puchetti was detected earlier than expected with subsequent decline of DIC (Assmy et al., 2017). Our results indicate that both Phaeocystis sp. and diatoms are sensitive to CO$_2$ limitation during highly productive periods in the west of Svalbard shelf. Although we cannot extrapolate our results beyond the study area, they are nevertheless relevant because the European sector of the Arctic contributes 50% of the annual Arctic Ocean plankton production (Arrigo, 2007).

Our results suggest that increased atmospheric CO$_2$ and the resulting increased air-sea CO$_2$ supply may stimulate Arctic gross
production of spring algal blooms under conditions of high biomass, high phytoplankton abundance, presence of nutrients and low $p$CO$_2$. In contrast, increased CO$_2$ may suppress gross production during summer conditions, when phytoplankton biomass and production are low, although the mechanisms involved are unknown. Moreover, our results are consistent with previous reports that the response of primary production to increased CO$_2$ is suppressed at water temperatures above 7°C (Holding et al., 2015). The expectation of GPP stimulation with increased CO$_2$ during spring blooms assumes that the nutrient supply will not be affected by concurrent changes. Increased stratification, due to Arctic warming and freshening may reduce vertical nutrient supplies from deeper layers (Sarmiento et al., 2004; Wassmann, 2011; Randelhoff et al., 2017), possibly reducing the intensity and timing of the spring algal bloom and, therefore, its carbon demand and potential CO$_2$ limitation. In contrast, areas currently covered by ice would, as the extent of ice continues to decline, support stronger algal spring blooms (Arrigo et al., 2008), which may experience episodic CO$_2$ limitation. The greatest increases in primary production in a future Arctic are expected in the Eurasian perimeter (Slagstad et al., 2015). However, current models do not consider the effects of episodic CO$_2$ limitation during the Arctic spring.

The global increase in CO$_2$ seems to have stimulated the primary production of terrestrial plants on a global scale due to CO$_2$ fertilization, possibly affecting the rate of increase in atmospheric CO$_2$ concentration and global temperatures (Denman et al., 2007; Leggett and Ball, 2015) during the last 10 years (Keenan et al., 2016). However, the existence of this slow-down remains controversial (Cowtan and Way, 2014; Karl et al., 2015). Given the relevant role that the Arctic Ocean plays as a sink for atmospheric CO$_2$ (Bates and Mathis, 2009), stimulation of Arctic GPP by CO$_2$ during highly productive periods in spring may strengthen the Arctic CO$_2$ sink and add, modestly, to biotic feedbacks that may affect global trends in atmospheric CO$_2$. However, negative effects of CO$_2$ on primary production of Arctic plankton communities in summer suggest that the “fertilization effect” of CO$_2$ on Arctic plankton, resulting in enhanced primary production during the short, 2–3 weeks, period of the spring bloom, maybe offset by negative effects through the much longer, 2–3 months, recycling phase, with potentially negative effects for the ecosystem. Whereas the mechanisms leading to enhanced GPP in Arctic plankton with increased CO$_2$ during spring appear clear, the mechanisms leading to suppression of GPP with CO$_2$ enrichment during summer need be resolved.

**AUTHOR CONTRIBUTIONS**

CD and MS-M designed the fieldwork and experiments. MS-M and PC executed the fieldwork and experiments. MS-M, PC, MC, EM, SK, and SA executed laboratory analyses. MS-M and CD analyzed the data and all authors contributed to the writing and editing of the manuscript.

**FUNDING**

This study is a contribution to the Carbon Bridge (RCN-226415) project funded by the Norwegian Research Council.

**ACKNOWLEDGMENTS**

We thank the crew of R/V Helmer Hanssen, I. Hendriks, M. Vernet, E. Falk, H. Hodal, and A. Granados for their help. J. Holding and L. Meire for valuable comments and V. Unkefer for improvements to the text. MS-M was supported by a La Caixa Ph.D. fellowship.
