Abstract

Using the Landauer-Büttiker formalism, we calculate the effect of structural twist on electron transport in conducting carbon nanotubes. We demonstrate that even a localized region of twist scatters the propagating $\pi$ electrons and induces the opening of a (pseudo-) gap near the Fermi level. The subsequent conductance reduction may be compensated by an applied axial magnetic field, leading to a twist-induced, giant positive magneto-conductance in clean armchair nanotubes.

Carbon nanotubes \cite{1-3} exhibit a range of unusual electronic properties associated with the morphology of these quasi-1D structures. Early one-electron theories successfully associated metallic or semiconducting behaviour with the chiral vector that characterizes a given nanotube \cite{4-6}. Further studies addressed the effect of atomic-level impurities \cite{7-10} and inter-tube interactions \cite{11-14} on electrical conductance, or magneto-transport \cite{15-18}. In parallel with the development of such one-electron theories, intensive studies of electron-electron correlations have been undertaken. Indeed, nonlinear current-voltage ($I-V$) characteristics have recently been observed \cite{19}, which are reminiscent of Luttinger liquid behaviour. An intriguing question remains however, namely whether other effects may augment or even dominate such nonlinearities in the transport properties of
nanotubes.

In this letter we predict that scattering of electrons from twistons may give rise to strongly non-linear $I - V$ characteristics. Twistons [20–22], associated with regions of axial twist in otherwise perfect nanotubes, are intrinsic defects that are frozen into nanotube bundles during their synthesis and hence cannot be ignored when discussing electron transport. Unlike ideal straight and defect-free nanotubes, which have been shown to exhibit conventional magneto-resistive behavior [23], we find that nanotubes containing twistons may behave in a very different way. In twisted tubes, we predict the occurrence of a giant positive magneto-conductance, an unexpected effect that by far exceeds the positive magneto-conductance associated with weak localisation in disordered tubes [24].

To compute the effect of a finite scattering region on transport in an otherwise perfect $(n, n)$ armchair nanotube, we use a parameterized four-state $(s, p_x, p_y, p_z)$ Hamiltonian, based on a global fit to Density Functional results for graphite, diamond and C$_2$ as a function of the lattice parameter [25]. A finite twiston is treated as a scattering region connecting two semi-infinite $(n, n)$ nanotubes. A recursive Greens function formalism is used to evaluate the transmission matrix $t$, describing the scattering of electrons of energy $E$ from one end of the semi-infinite nanotube to the other [26]. The differential electrical conductance at bias voltage $V_{\text{bias}}$ is related to scattering properties at energy $E = E_F - eV_{\text{bias}}$ by the Landauer formula $G = G_0 \text{Tr} \left\{ t^\dagger t \right\}$, where $G_0 = 2e^2/h$ is the conductance quantum. A twiston is formed by introducing a small angular distortion between neighboring axial slices within the scattering region. This is shown schematically in the inset of Fig. 1(a), which displays the local shear distortion within the unit cell of length $L$, containing two axial slices. The perturbation to the Hamiltonian matrix enters through the scaling of the nearest-neighbor hopping integrals that follow the changes in C-C bonds $r_1$ and $r_2$.

Fig. 1 shows the differential conductance for a straight and twisted (10, 10) nanotube. In the straight nanotube of Fig. 1(a), the non-degenerate bands, which cross near $E_F$, open up two conductance channels at this energy. Additional conduction channels follow as an increasing number of subbands appear near $E_F - eV_{\text{bias}}$ at higher bias voltages. In the
presence of a localized twiston, the differential conductance is suppressed at all energies, in particular near the Fermi level. This is shown in Fig. 1(a) for a finite-length twiston, with a total twist of 36° extending over 100 unit cells or ≈24.6 nm. The occurrence of a conductance gap near $E_F$ suggests that electron scattering by a finite twiston can be viewed as a tunneling phenomenon.

For comparison with Fig. 1(a), Fig. 1(b) shows results for a nanotube subject to an infinitely long uniform twist $d\theta/dl$. This shows that that a localized or infinitely long twist opens up a conductance gap $\Delta$ near $E_F$. The predicted gap in the presence of infinitely long twists is shown in Fig. 1(c) and agrees with results of Refs. [20] and [21].

In the following, we discuss the dependence of the conductance gap on the twist distortion $d\theta/dl$, the spatial extent of the twiston, and an axially applied magnetic field. As shown in Fig. 1(c), we find that for a range of $(n, n)$ tubes subject to an infinitely long twist, the magnitude of the conductance gap $\Delta$ increases linearly with increasing twist distortion to its maximum value $\Delta_{\text{max}}$, and decreases thereafter. For an $(n, n)$ nanotube, we find the maximum value of the conductance gap $\Delta_{\text{max}}$ to be achieved at an “optimum tube twist” value $(d\theta/dl)_0 \approx An^{-2}$ (with $A = 620^\circ$/nm), which depends on the chiral index $n$. The dependence of $\Delta_{\text{max}}$ on the optimum tube twist $(d\theta/dl)_0$ corresponds to the envelope function in Fig. 1(c), and is well approximated by $\Delta_{\text{max}} \approx \Delta(d\theta/dl)_0 \approx 1.30 \text{ eV} \left(1 - e^{-0.21(d\theta/dl)_0}\right)$, with $(d\theta/dl)_0$ in $^\circ$/nm units.

Details of conductance changes due to localized twistons, such as those of Fig. 1(a), are shown for small bias voltages in Fig. 2(a). In the present case, we subjected a straight $(10, 10)$ nanotube to finite twists $\Delta \theta$ extending over 100 unit cells. We find that the conductance pseudo-gap associated with finite twistons is accompanied by conductance oscillations at small bias voltages. A tube subject to an infinitely long twist, on the other hand, possesses a real gap with no such oscillations. The zero-bias conductance as a function of the twist angle for finite twistons extending over 100 unit cells is presented in Fig. 2(b) for a range of tube sizes. This type of conductance behaviour is reminiscent of that associated with tunneling through a potential barrier, where the twist-induced gap is analogous to the height
of the barrier. These results, when combined, clearly demonstrate that finite twistons yield
non-linear $I - V$ characteristics.

It must be stressed that the degree of twist required to open a pseudo-gap is small. For
example in the finite (10,10) carbon nanotube of Fig. 2(a), $\Delta \theta = 20^\circ$ over 100 unit cells
is equivalent to $d\theta/dl \lesssim 1^\circ/\text{nm}$ only. The resulting perturbation to the Hamiltonian is
therefore well within the limits of our model, where the twist is viewed as a frozen-in defect
to the nanotube at low temperatures [22].

We now consider the effect of a uniform magnetic field on transport in straight and
twisted nanotubes. Axially applied magnetic fields produce an Aharonov-Bohm effect in
carbon nanotubes [16,17,27], which in the clean limit arises from the opening and closing
of a band gap at the Fermi level. In the presence of a twiston, we now demonstrate that
the reverse effect can occur, namely that an axial magnetic field can remove the twiston-
induced conductance gap, resulting in a positive magneto-conductance. Our results show
that a magnetic field may restore the zero-bias conductance of twisted armchair nanotubes
from an essentially vanishing value to near half of the initial zero-twist value. To understand
this behaviour, consider the simplest model of a twisted nanotube, depicted in the inset of
Fig. 2(a). Let us assume that a single $\pi$ orbital per carbon atom is needed to describe the
conductance changes near $E_F$. In CNT’s the $k$ vectors perpendicular to the tube surface are
quantised and from

$$
\Delta(k) = |\gamma_0 + \gamma_1 e^{i k \cdot r_1} + \gamma_2 e^{i k \cdot r_2}|
$$

in the untwisted armchair CNT the tight-binding dispersion relation can be calculated to
give

$$
E_{1D}(k) = \pm \gamma \left( 1 + 4 \cos\left( \frac{q \pi}{n} \right) \cos\left( \frac{ka}{2} \right) + 4 \cos^2\left( \frac{ka}{2} \right) \right)^{1/2}.
$$

The structural twist is then modeled by changing the relative strength of the hopping integral
$\gamma_i$ along the neighbor vector $r_i$ with respect to the untwisted reference value $\gamma_0 = 1$. Upon
exposing a twisted tube to a magnetic field we multiply by a phase factor [17] and find
that the energy gap between the top of the valence and bottom of the conduction band of a twisted tube changes to

$$\Delta(k) = |1 + \gamma_1 e^{i k \cdot r_1} e^{i \phi} + \gamma_2 e^{i k \cdot r_2} e^{i \phi}|.$$  \hspace{1cm} (1)

The phase $\phi = 2\pi \Phi/\Phi_0$ depends on the ratio between the magnetic flux $\Phi$ trapped in the tube and the fundamental unit of flux $\Phi_0 = h/e$. Note that the fundamental unit of flux used in this paper is twice the flux quantum, $\Phi_0 = h/2e$. The fundamental gap $\Delta = \Delta(k_0)$, occurring at $k_0$, is the minimum value found in the Brillouin zone. We also note that $\Delta = 0$ for an undistorted tube in zero field.

In view of the twisted tube morphology defined in Fig. 1(a), it is convenient to introduce the quantity $\alpha = k \cdot r_1 = -k \cdot r_2$. From Eq. (1) we find that $\Delta(k) = 0$ only if $(\sin \phi/\sin \alpha) = (\gamma_1 - \gamma_2)$ and $(\cos \phi/\cos \alpha) = (-\gamma_1 - \gamma_2)$. Combining these equations, we find that the fundamental gap closes if

$$\cos 2\phi = \frac{(\gamma_1^2 + \gamma_2^2) - (\gamma_1^2 - \gamma_2^2)^2}{2\gamma_1 \gamma_2}$$ \hspace{1cm} (2)

and

$$\cos 2\alpha = \frac{1 - \gamma_1^2 - \gamma_2^2}{2\gamma_1 \gamma_2}.$$ \hspace{1cm} (3)

In other words, according to Eq. (3), the twist-induced fundamental gap closes again, once the $(n, n)$ nanotube is exposed to a magnetic field $B$

$$B = B_c \arccos \left( \frac{(\gamma_1^2 + \gamma_2^2) - (\gamma_1^2 - \gamma_2^2)^2}{2\gamma_1 \gamma_2} \right)$$ \hspace{1cm} (4)

along its axis, where $B_c = 2.28 \times 10^4$ T/n$^2$. According to Eq. (3), the longitudinal wavevector $k_0$, at which the fundamental gap vanishes, must satisfy the condition

$$k_0 \cdot r_1 = \frac{1}{2} \arccos \left( \frac{1 - \gamma_1^2 - \gamma_2^2}{2\gamma_1 \gamma_2} \right).$$ \hspace{1cm} (5)

The above heuristic model also demonstrates why the exact result yields $G\approx G_0$ for the zero bias conductance in presence of a non-zero twist and flux, rather than the value $G = 2G_0$
for a twist-free tube in zero field. In the latter case, the two open scattering channels at $E_F$
correspond to values of $\alpha$ (or wavevector $k$) of opposite sign. For a given nonzero flux $\Phi$
and a corresponding sign of the phase $\phi$, $(\sin \phi / \sin \alpha) = (\gamma_1 - \gamma_2)$ can be satisfied by only
one of these channels.

In summary, we have analyzed for the first time the scattering properties of finite-size
twistons and shown that these introduce non-linear $I-V$ characteristics associated with
the opening of a pseudo-gap at $E_F$, thus effectively quenching the nanotube conductance.
This conductance gap can be closed in an axial magnetic field, leading to a giant positive
magneto-conductance. At small bias voltages, the conductance of a twisted tube in nonzero
field can reach up to half the ballistic conductance value of a straight tube in zero field.
