We report on the scaling of basic hadronic observables in lattice QCD with $N_f = 2$ maximally twisted Wilson dynamical quarks. We give preliminary results for some of the Gasser–Leutwyler low energy constants, the chiral condensate and the average mass of $u$ and $d$ quarks.
 Scaling and low energy constants in $N_f = 2$ Mm-LQCD

Roberto Frezzotti and Gregorio Herdoiza

1. Introduction and setup

In this contribution we report on the scaling of basic hadronic observables and present preliminary results for some of the Gasser–Leutwyler low energy constants in lattice QCD with $N_f = 2$ dynamical quarks. We choose the lattice formulation with tree-level improved gauge action and maximally twisted Wilson quarks \cite{1}, which can be efficiently studied by means of state-of-the-art simulation algorithms, such as the one we adopted \cite{3}, and leads to physical observables free of $O(a)$ cutoff effects \cite{3}. In this way it is possible to study the theory with pion masses down to about 300 MeV, three different lattice resolutions and spatial lattice sizes of 2–3 fm. The main parameters of the simulations employed for the present analysis are summarized in table 1 of Ref. \cite{4}. For all ensembles we have $m_{PS}L \geq 3$, with the lowest values (namely 3.0, 3.3, 3.3 and 3.5) being obtained in the ensembles C6, B1, C1 and C5, respectively. For details about our lattice setup, the evaluation of quark propagators and any undefined notations we refer to Refs. \cite{1, 3}.

1.1 Tuning to maximal twist

The values of $\kappa$ in table 1 of Ref. \cite{4} result from implementing maximal twist as discussed here. The formal definition of maximal twist for Wilson quarks reads: $m_R = 0$ and $\mu_R = O(a^0)$ for all lattice spacings $a$ as $a! 0$, with renormalized mass parameters

$$\mu_R = Z_\mu \mu = Z_p^\dagger \mu \ , \quad m_R = Z_{\gamma_0}^\dagger (m_0 \ m_{\text{crit}}) = Z_\mu Z_p^\dagger m_{\text{PCAC}} \ :$$

(1.1)

At the non-perturbative level any legitimate estimate of the critical mass, $m_{\text{crit}}$, is affected by terms of $O(a\Lambda_{QCD}^2)$ and $O(a\mu\Lambda_{QCD})$, which however do not invalidate the definition of maximal twist. Following Refs. \cite{5, 6}, for each $\beta$ (and $\mu$) one can define maximal twist by demanding

$$\text{amp}_{\text{PCAC}}(\beta \mu) \ \frac{a^4 \sum \nabla_0 \bar{\chi}_0 \gamma_5 \tau^1 \chi \times \bar{\chi}_0 \gamma_5 \tau^1 \chi^\dagger(0) \gamma_0}{a^3 \sum \nabla_0 \bar{\chi}_0 \gamma_5 \tau^1 \chi \times \bar{\chi}_0 \gamma_5 \tau^1 \chi^\dagger(0) \gamma_0} \beta \mu = 0 \ ;$$

(1.2)

at values of $x_0$ and $L$ so large that the (charged) one-pion state dominates the correlators on the r.h.s. This prescription fixes the lattice artifact $O(a\Lambda_{QCD}^2)$ in the critical mass in such a way that, provided $\mu \ll a^2 \Lambda_{QCD}^3$, the dominating (relative) cutoff effects left-over in physical observables\footnote{Here quark bilinears are written in the unphysical quark basis $(\chi, \bar{\chi})$ where the Wilson term has its standard form.} are expected to be numerically as small as $O(a^2\Lambda_{QCD}^2)$. A detailed analysis \cite{3} shows that such cutoff effects are actually products of (two) terms of order $a\Lambda_{QCD}$, $a\mu$ (negligible for small $\mu$) or $a^3 \Lambda_{QCD}^4 \mu^4$ (higher order in $a$, but enhanced for small $\mu$).

In practice, as we are interested in simulations with $\mu \ll \mu_{\text{LOW}}$, in order to minimise the work for the tuning of $\kappa$, we choose to impose the condition \footnote{Concerning the $\pi^0$-mass, in Ref. \cite{6} it is argued that the possibly large $O(\alpha^2)$ artifact on this observable is merely due to the large value taken by a (continuum) matrix element present in the Symanzik expansion of all lattice correlators where the $\pi^0$ state contributes, rather than to the presence of dimension six operators with large coefficients in the Symanzik effective action. This implies that this cutoff effect represents an exceptional, though important case.} only for $\mu = \mu_{\text{LOW}}$. With this choice, in the region where $\mu < \Lambda_{QCD}$ we expect \footnote{Here quark bilinears are written in the unphysical quark basis $(\chi, \bar{\chi})$ where the Wilson term has its standard form.} the numerically dominating cutoff effects on physical observables to be modulated by factors of $\mu_{\text{LOW}}/\mu$ as $\mu$ is varied (for instance one can have contributions from terms of order $(a\Lambda_{QCD}\mu_{\text{LOW}}/\mu)^2$). With $\kappa$ fixed according to the criterion described above, maximal twist is implemented properly, provided

$$\mu \ll \mu_{\text{LOW}} \quad C a^2 \Lambda_{QCD}^3 \ ;$$

(1.3)
where the coefficient \( C \) has to be learned from numerical experiment. In our \( N_f = 2 \) setup, \( C = 2 \) (assuming \( \Lambda_{QCD} = 250 \) MeV) is essentially determined by the condition that MC simulations exhibit no metastabilities (see e.g. Ref. \( [8] \), sect. 5.5). At fixed \( \mu_R \) a smooth approach to the continuum limit is to be expected if maximal twist has been realized at (approximatively) the same value of \( \mu_R \) in physical units for all the considered lattice resolutions.

Our practical implementation of maximal twist is illustrated by Fig. 1a, where we show \( m_R r_0 \propto m_{PCAC} \) vs. \( \mu_R r_0 \propto \mu \) for \( \beta = 4.05, 3.9 \) and 3.8 (use of renormalized quantities eases the comparison). Details on \( r_0 = a \) and \( Z_P \) (actually \( Z_P(\overline{MS}, 2 \text{ GeV}) \)) are given below.

For \( \beta = 4.05 \) and 3.9 we could fulfill our criterion for maximal twist at \( \mu_R \) with good statistical precision: as shown in Fig. 1a, \( m_R = \mu_R \) is consistent with zero within the statistical error, that we call \( \epsilon = \mu_R \). As a rule of thumb, we demand \( \epsilon = \mu_R \) to be such that, numerically, \( a \Lambda_{QCD} \epsilon = \mu_R \). Considering the form of the \( d = 5 \) term in the Symanzik effective Lagrangian one finds in fact that \( a \Lambda_{QCD} \epsilon = \mu \) is the expected order of magnitude of the unwanted (relative) cutoff effects that may contaminate physical observables if, due to numerical error, \( m_{PCAC}(\beta, \mu) \) takes the value \( \epsilon Z_A \), rather than zero. Having no a priori control on the coefficients of this order of magnitude estimate, we can only learn from the numerical experience of a scaling test (involving our statistically most precise observables, \textit{i.e.} \( f_{PS} \) and \( m_{PS} \)) whether our rule of thumb yields a sufficiently accurate tuning to maximal twist.

At \( \beta = 3.8 \) our implementation of maximal twist was not as precise as wished due to the long-range statistical fluctuations that, for \( \mu_R \), 0 \( \mu r_0 \), were observed in our MC simulations (see Ref. \([4]\) for information on autocorrelation times). These fluctuations, which increase in MC-time length and (weakly) in amplitude as \( \mu \) decreases, have a major impact on those observables, such as the plaquette and \( am_{PCAC} \), that are not continuous at the Singleton-Sharpe (1st order) lattice phase transition \([8, 3]\), rendering somewhat problematic the estimate of their statistical errors. This is manifest in Fig. 1a from the two non-coinciding points obtained for the lowest \( \mu_R \) at \( \beta = 3.8 \), coming from two independent simulations at slightly different \( L \) (ensembles A1 and A5 in tab. 1 of Ref. \([4]\)). In this case, the quoted (possibly underestimated) statistical errors are larger than required by our rule of thumb.
1.2 Evaluation of \( r_0 \)

In our scaling analyses we employ the Sommer scale \( r_0 \) \[1\] to eliminate the lattice spacing \( a \). This is meant only as an intermediate step. In the end \( r_0 \) will be eliminated in favour of \( f_\pi \) (i.e. \( f_{PS} \) at the physical point) to get the scale for all dimensionful quantities. The value of \( r_0 \) for the various ensembles was obtained with a better than 0.5\% accuracy, starting from Wilson loops made out of HYP-smeared temporal links \[11\] and APE-smeared spatial links. Employing several interpolating operators for static quark-antiquark (\( Q\bar{Q} \)) states, corresponding to different spatial smearings, leads to a matrix of correlators, from which the (lowest) levels of the potential \( V_{Q\bar{Q}}(r) \) are estimated by solving a generalized eigenvalue problem. A fit to the \( r \)-dependence of the ground state gives \( r_0 (\mu) = a \). For each \( \beta \), the latter shows a rather mild \( \mu \)-dependence, which is well described by a first order polynomial in \( \mu^2 \). The following values, extrapolated to the chiral limit and denoted simply as \( r_0 = a \), will be used in this work (those at \( \beta = 4 \Omega 5 \) and \( \beta = 3 \Omega 8 \) must be viewed as preliminary):

\[
\begin{align*}
\beta = 4 \Omega 5: & \quad r_0 = a_{\beta=4.05} = 6.61(3) \quad r_0 = a_{\beta=3.9} = 5.22(2) \quad r_0 = a_{\beta=3.8} = 4.46(3) \\
\end{align*}
\]

Note that a fit by a second order polynomial in \( \mu \) gives compatible results. An overview of the results for \( r_0 (\mu) \) for all \( \beta \)'s is given in Fig. \[3\], where the axes are normalized in terms of the appropriate chirally extrapolated \( r_0 \). For \( \beta = 3 \Omega 8 \) the point at the lowest \( \mu \)-value (ensemble A1) is preliminary and carries a still poorly estimated statistical error. It was hence not used in the extrapolation to the chiral limit. More details will be given in a forthcoming publication.

2. Charged pion sector: general remarks

In the charged pseudoscalar (PS) meson sector our raw results for \( f_{PS} \) and \( m_{PS}^2 \) from simulations at \( \beta = 4 \Omega 5 \) and \( 3 \Omega 9 \) with \( L > 2 \) fm, once expressed in units of \( r_0 \), exhibit an excellent scaling behaviour, see Fig. 4 of Ref. \[4\]. Also the corresponding results at \( \beta = 3 \Omega 8 \), in spite of the uncertainties on the implementation of maximal twist and the estimate of statistical errors, appear consistent with a very good scaling behaviour in the mass range \( m_{PS} = (350 \rightarrow 600) \) MeV. These findings are in agreement with the expectation that cutoff effects are small in the absence of \( O(a) \) artifacts. In particular in the charged PS-meson sector it is known \[5, 6\] that, for small quark masses \( \mu_R \), \( m_{PS}^2 \) differs from its continuum counterpart only by terms of \( O(a^2 \mu_R) \) and \( O(a^4) \), while \( f_{PS} \) has discretization errors of \( O(a^2) \). This property holds for any volume \( L^3 \) (sufficiently large to make pions much lighter than other states) and is not affected by the lattice artifact on the neutral PS-meson mass. \(^3\) In other words, to order \( a^2 \) the cutoff effects on \( m_{PS}^2 \) and \( f_{PS} \) are like in a chirally invariant lattice formulation. The use of continuum chiral formulae to describe the volume and quark mass dependences of our data in the charged PS-meson sector is thus well justified.

2.1 Estimates of \( Z_P \) and of the renormalized quark mass

In the study of the scaling of the renormalized quark mass \( \mu_R \) one needs the renormalization constant \( Z_P (\beta; a \mu) \) at a common scale \( q \) for all the considered values of \( \beta \). This renormalization constant, as well as the scale-independent one \( Z_A (\beta) \), was also employed in Fig. \[4\]. \(^4\) Preliminary

\(^3\)The relation of a possibly large and negative lattice artifact on \( m_{PS}^2 \) to metastabilities in MC simulations has been discussed in Refs. \[7, 8\]. Such metastabilities are not observed in the simulations we consider here \[9\].

\(^4\)For the renormalization constants we keep the names they are given in the literature for the standard (untwisted) Wilson quark lattice formulation, as obviously their values do not change with respect to the untwisted Wilson case.
O(a) improved estimates of the renormalization constants of quark bilinear operators are reported in Ref. [12]. There the results for $Z_A$ are rather precise (at the 1.5% level), while the quoted uncertainties on $Z_P$ are still substantially larger.

In view of this situation, in our scaling analysis of $\mu_R$ we do not use the values of $Z_P$ quoted in Ref. [12]. We rather employ the scale- and scheme-independent ratios $Z_P(\beta; a q) = Z_P(\beta_{ref}; a_{ref} q)$, which we extract with a statistical accuracy of 1% from the relation (exact up to $O(a^2)$ terms)

$$Z_P(\beta; a q) = Z_P(\beta_{ref}; a_{ref} q) = \mu(\beta; m_{PS} r_0 = 1; L = r_0 \ ' 5) = \mu(\beta_{ref}; m_{PS} r_0 = 1; L = r_0 \ ' 5);$$ (2.1)

in order to compare the values of $\mu_R(\beta; a q) Z_P(\beta_{ref}; a_{ref} q)$ at different values of $\beta$ and of the PS-meson mass. In eq. (2.1), $a\mu(\beta; m_{PS} r_0 = 1; L = r_0 \ ' 5)$ is the value of $a\mu$ for which, at a given $\beta$ and $L = r_0 \ ' 5$, one finds $m_{PS} r_0 = 1$. The scaling is obviously not affected by the extra overall factor $Z_P(\beta_{ref}; a_{ref} q)$, which is removed in the end (in order to give an idea of the values of the renormalized quark masses). In the following we choose $\beta_{ref} = 3.9$, where we most reliably know (see Ref. [12]) $Z_P(\beta_{ref}; a_{ref} q)$, we evaluate for $\beta = 4.05$ and $\beta = 3.8$ the $Z_P$-ratios from eq. (2.1) and we finally obtain estimates of $\mu_R(\beta; a q)$ at $q = 2$ GeV in the \( \overline{\text{MS}} \) scheme for all $\beta$’s. An important drawback of this method is the fact that cutoff effects stemming from data obtained at different $\beta$-values mix up in the quark mass renormalization, which in general may fake the genuine $a$-dependence and cast doubts on the reliability of any continuum extrapolation. Nevertheless, since our data for $\beta = 4.05$ and $3.9$ show no statistically significant cutoff effects in the relation of $f_{PS}$ to $m_{PS}^2$ and in the values of $\mu_R(\beta; a q) Z_P(\beta_{ref}; a_{ref} q)$, we can obtain an estimate of the continuum limit of $\mu_R$ (in units of $r_0$) by taking an average of the results at these two $\beta$-values. A similar remark holds for the determination of $\delta_0$ and the chiral condensate in sect. 4.3. As discussed below, for all observables we associate to our continuum limit estimates a conservative systematic error obtained by comparing them to the corresponding results from data at $\beta = 3.8$.

2.2 About taking the continuum, thermodynamical and chiral limits

It is well known that matching simulation data obtained at finite $L$ and for $m_{PS} \ 300$ MeV to the physical pion point requires a delicate analysis. The impact of residual $O(a^2)$ effects (even if small) on such an analysis might be enhanced if the continuum limit is performed as the last step. It is therefore advisable to perform first a continuum limit extrapolation at different (suitably chosen) fixed physical conditions and then use Chiral Perturbation Theory ($\chi$PT) to correct for finite size effects and reach the physical pion point. This is the strategy we follow in sect. 4.1.1, based on the results of the scaling test presented in sect. 3.1. As far as one is concerned with data, such as those at $\beta = 4.05$ and $3.9$, where no significant cutoff effects are observed, a conceptually equivalent approach is that of performing a combined analysis of all data by means of continuum $\chi$PT formulae. The outcome of this approach, which is detailed in Ref. [9], is summarised in sect. 4.1.2. For comparison we also discuss in sect. 4.1.3 the results of fits to continuum $\chi$PT formulae where the data corresponding to different lattice spacings are treated separately.

$^5$This value of $m_{PS} r_0$ was chosen so as to lie in the region where errors from interpolation to the reference mass and cutoff effects are smallest.
3. Charged pion sector: scaling test

Here we analyse the scaling behaviour of the charged PS-meson decay constant and the renormalized quark mass as a function of \( \beta = \beta_0 = \alpha \) at fixed values of \( m_{\text{PS}} \) and \( L = r_0 \). The renormalization and scaling conditions are as follows: (i) \( r_0^2 F_{Q\bar{Q}}(r_0) = 1 \pm 5 \) (with \( F_{Q\bar{Q}} \) the static interquark force), which allows to trade \( \beta_0^2 = 6 = \beta \) with \( r_0 = \alpha \); (ii) \( m_{\text{PS}r_0} = \text{constant} \pm 0.0 \pm 0.0 \pm 0.0 \pm 1.0 \pm 1.0 \pm 1.2 \), which eliminates \( \mu \) in favour of \( m_{\text{PS}} \); (iii) fixed spatial volume \( L^3 \) for \( (2.2 \text{ fm})^3 \), which corresponds to \( L = r_0 = 5 \).

3.1 Scaling and preliminary continuum limit estimates

The typical relative statistical errors are (conservatively) estimated to be about 0.7% for \( m_{\text{PS}r_0} \), 1.0% for \( f_{\text{PS}r_0} \) and 1.5% for \( \mu_{\text{PS}r_0} \). In the latter case, besides the error on \( r_0 = \alpha \), only the uncertainty (typically about 1.2%) on the \( Z_p \)-ratios (see eq. (2.1)), is taken into account and hence shown in Fig. 3. The error on \( Z_p(\beta_{\text{ref}}, a_{\text{ref}}q) \) is omitted here, as it plays no role, while in sect. 4 it is taken into account, as it matters for the final values of \( B_0 \), the chiral condensate and \( m_{\text{ud}} \).

The condition (i) is immediately fulfilled once all quantities are expressed in units of \( r_0 \). As for the other two conditions, we first implement the condition (iii) by “moving” via resummed \( \chi \text{PT} \) formulae (see Ref. [14]) the data for \( f_{\text{PS}r_0} \) and \( m_{\text{PS}} \) from the simulation volume \( L^3 \) to the reference one \( L^3_{\text{ref}} \). As simulations were done with \( L \geq (2.0 \pm 2.4) \) fm, the numerical change in the data is very tiny (never larger than 0.7%) and thus statistically almost irrelevant. Then, in order to match the reference values of \( m_{\text{PS}r_0} \) given in (ii), we perform interpolations (in few cases also short extrapolations) of the values of \( f_{\text{PS}r_0} \) and \( \mu_{\text{PS}r_0} \). For this purpose we try both (low order) polynomial and \( \chi \text{PT} \)-inspired fits to the data. The spread among the different fits with good \( \chi^2 \), whenever statistically significant, is added linearly to the interpolation error. In this way one ends up with the blue filled circle data points (and errorbars) in the Figs. 2 and 3.

For each value of \( m_{\text{PS}r_0} \) we obtain preliminary estimates of the continuum limit values of \( f_{\text{PS}r_0} \) and \( \mu_{\text{PS}r_0} \) by fitting to a constant (red line in the figures) only the data points from simulations at \( \beta = 4 \pm 5 \) and \( \beta = 3.9 \). The results, with only statistical error from the continuum extrapolation, are shown in red in Figs. 2 and 3. In all cases the difference between the result of the continuum extrapolation and the central value (blue filled circle point) for \( \beta = 3.9 \) is taken as an estimate of the systematic error (indicated with a green cross placed at a slightly negative value of \( a \)) on the continuum limit result. Since the latter is obtained by simply taking a weighted average of the results at \( \beta = 4 \pm 5 \) and 3.9, the introduction of such an error appears necessary. Moreover, the quality of the data in the figures suggests that the way we estimate this systematic error is rather conservative. Finally, the green crosses (and errorbars) appearing in Figs. 2 and 3 at \( a = r_0 \) \( 0 \pm 5 \) show, whenever the displacement is larger than one standard deviation, where the actual data would move if one were correcting for the leading effect of the numerical error (denoted by \( \varepsilon \) in sect. 3.2) in imposing \( m_{\text{PCAC}} = 0 \). We refer to the results of such a correction (explained in sect. 3.4) as to “data moved to maximal twist”.

3.2 About “moving data to maximal twist”

The procedure of “moving data to maximal twist” can be seen as a way of testing whether statistical errors in the tuning to maximal twist have any significant impact on the observables of interest. If one has \( Z_{Am_{\text{PCAC}}} = \varepsilon \) (rather than zero), the effective twist angle in the Symanzik
Scaling and low energy constants in $N_f=2$ \textit{M}\textit{m}-\textit{LQCD}

Roberto Frezzotti and Gregorio Herdoiza

Figure 2: Scaling plots of $f_{PS}r_0$ vs. $(a/r_0)^2$ at fixed values of $m_{PS}r_0$ (increasing from bottom to top). See text for a detailed explanation of the symbols.

Lagrangian is $\alpha = \pi/2$ \th with $\tan \theta = m_R = \mu_R = \epsilon = \mu$. Treating $\epsilon$ as an $O(\alpha^0)$ quantity and neglecting $O(\alpha \theta)$ and $O(\alpha^2)$ effects, the consequences of a deviation from maximal twist are in general twofold. First, the effective renormalized quark mass becomes $M_R = (\mu_R^2 + m_R^2)^{1/2} = \mu_R = \cos \theta$. Second, in all operator matrix elements any operator formally non-invariant under axial-$\tau^3$ transformations must be reinterpreted consistently with the twist angle being $\alpha = \pi/2$ (rather than $\pi=2$). As a consequence, once the hadronic states of interest are correctly identified, simple $\theta$-dependent formulae can be derived that allow to extract properly the matrix elements of operators non-invariant under axial-$\tau^3$ transformations. For instance, the (renormalized) operator $Z V \bar{\chi} \gamma_\mu \tau^2 \chi$ (written in the basis where the Wilson term has its standard form) coincides with $\cos \theta A_{\mu R} + \sin \theta V_{\mu R}$, where $A_{\mu R}$ ($V_{\mu R}$) is the physical axial (vector) current. Consequently one finds $< \pi^1 Z V \bar{\chi} \gamma_\mu \tau^2 \chi \Omega > \sim_{\mu_R \neq \mu_R} = \cos \theta < \pi^1 A_{\mu R} \Omega > \sim_{\mu_R \neq \mu_R} = O(\alpha \theta \mu_R^2)$, which implies $m_{PS} f_{PS}^2 \sim_{\mu_R \neq \mu_R} = \cos \theta + O(\alpha \theta \mu^2)$.

From these arguments it follows that $m_{PS}$ data need not be moved, while the data for $\mu_R$ and $f_{PS}$ are “moved to maximal twist”, up to $O(\alpha \mu_R^2)$, by dividing them by $\cos \theta$, where $\theta$ is obtained from the (interpolated) actual values of $\epsilon$ and $\mu_R$ in our data sets. It turns out that the change implied by this correction is larger than one standard deviation (of the uncorrected data) only for the two smallest reference values of $m_{PS}r_0$ at $\beta = 3.8$. After such correction all the data points at $\beta = 3.8$ (including the two most chiral ones) fit very nicely into the scaling picture suggested from the corresponding data at $\beta = 3.9$ and $\beta = 4.05$.

However, any data where the above correction was statistically relevant can be hardly used for a continuum extrapolation, because the residual (uncorrected) $O(\alpha \theta)$ lattice artifacts depend on the details of the numerical errors at the different $\beta$-values and hence need not to scale as $a^0$. Nevertheless, at a more qualitative level, the procedure of “moving data to maximal twist” confirms that, even at $\beta = 3.8$ (i.e. $a \sim 0.1$ fm), the lattice artifacts in the charged PS-meson sector appear to be quite small, provided maximal twist is implemented precisely, e.g. according to the criteria of sect. [11]. In fact such a precise implementation is rather hard to achieve in the case of our
as well as of the average light quark mass, where out \[4\] to describe well our data at different volumes (and for to the parameters (denoted by CDH). In the following we always use the CDH expressions for 4. Charged pion sector: physical results

Here we discuss the description of our \( m_{PS}\)- and \( f_{PS}\)-data by means of continuum \( \chi \)PT for \( N_f = 2 \) QCD and give preliminary estimates of the low energy constants (LEC) \( \tilde{l}_3, \tilde{l}_4, B_0 \) and \( f_0, \) as well as of the average light quark mass, \( m_{ud}, \) and the chiral condensate.

We employ the following continuum NLO \( \chi \)PT formulae \[13, 14\] to simultaneously describe the dependence of \( m_{PS} \) and \( f_{PS} \) on the bare quark mass (\( \mu \)) and on the finite spatial size (\( L \)):

\[
m_{PS}^2 (L) = 2 B_0 \mu K_m^2 (L) \ 1 + \xi \ln \left(2 B_0 \mu = \Lambda_3^2\right) ; \tag{4.1}
\]

\[
f_{PS} (L) = f_0 K_f (L) \ 1 + 2 \xi \ln \left(2 B_0 \mu = \Lambda_3^2\right) ; \tag{4.2}
\]

where \( \xi = 2 B_0 \mu = (4 \pi f_0)^2 \) and \( K_m, K_f (L) \) account for finite size (FS) effects. The LEC \( \tilde{l}_3, \tilde{l}_4 \) are related to the parameters \( \Lambda_3, \mu \) introduced in eqs. (4.1)–(4.2) through \( \tilde{l}_3, \tilde{l}_4 = \log (\Lambda_3^2 - m_\pi^2) \). The expressions for \( K_m, K_f (L) \) at NLO (denoted as GL) read \[13\]:

\[
K_{GL}^m (L) = 1 + \frac{1}{2} \xi \tilde{g}_1 (\lambda) \quad \text{and} \quad K_{GL}^f (L) = 1 + 2 \xi \tilde{g}_1 (\lambda),
\]

where \( \lambda = \sqrt{2 B_0 \mu L^2} \) and \( \tilde{g}_1 (\lambda) \) is a known function. A convenient way to include higher order \( \chi \)PT terms in the description of FS effects on \( m_{PS} \) and \( f_{PS} \) is provided by the formulae of Ref. \[14\] (denoted by CDH). In the following we always use the CDH expressions for \( K_{m,f} (L) \), which turn out \[3\] to describe well our data at different volumes (and for \( m_{PS} \) better than GL formulae).

In all the analyses below physical units are introduced as follows: the experimental values, \( f_\pi = 130 \) MeV and \( m_{\pi^0} = 135 \) MeV, \( f_\pi \) are exploited to determine first the \( \mu \)-value, \( \mu_\pi \), corresponding to the “physical point” through \( m_{PS} = m_{PS} \mu_\pi = m_{\pi^0} = f_\pi \), and then (depending on the analysis) the value of \( r_0 f_\pi \), or \( a f_\pi \). The latter allows to express all quantities in units of \( f_\pi \).

\[6\] We use the convention \( f_0 = \sqrt{2 B_0} \), i.e. the normalization \( f_\pi = 130 \) MeV.

\[7\] The \( \pi^0 \)-mass input is chosen in view of the absence of electromagnetic effects in our lattice QCD simulations.
4.1 Chiral fits and continuum estimates of LEC

As anticipated in sect. 2.2, given the good scaling behaviour of our data, we present preliminary continuum estimates of LEC and \( m_{ud} \) that stem from two analyses – see sects. 4.1.1 and 4.1.2. In sect. 4.1.3 we give the corresponding results that are obtained at two fixed lattice spacings, \( a(\beta = 4.05) \) and \( a(\beta = 3.9) \). The latter results will serve mainly for estimating (in the way detailed below) the systematic error due to residual \( O(a^2) \) cutoff effects.

Concerning other systematic errors, we note: (i) residual uncertainties in the CDH-formulae for FS effects are small, compared to other systematic errors – see the discussion in Ref. [3]; (ii) the possible impact of NNLO corrections to the formulae (4.1)–(4.2) for the quark mass dependence is minimized by taking out of the analyses the points with highest values of \( \mu_R \) (we checked that fits are stable if we leave out data with \( \mu_R > 500 \text{ MeV} \) – more details in a forthcoming publication).

4.1.1 \( \chi \)PT fits in the continuum

Following the strategy presented in sect. 2.2 one can estimate the continuum limit values of \( f_{PS} r_0 \) and \( \mu_R r_0 \) at fixed values of \( m_{PS} r_0 \) and \( L_{\text{ref}}=r_0 \), as reported in sect. 3.1. Considering \( f_{PS} r_0 \) and \( m_{PS} r_0 \) as functions of \( \mu_R r_0 \) allows for direct use of the \( \chi \)PT formulae (4.1)–(4.2) to bring our data from \( L_{\text{ref}} = 2.2 \text{ fm} \) to infinite volume and parameterise their quark mass dependence. Leaving out the point corresponding to \( m_{PS} r_0 = 1.25 \), the data are well described by our fit ansatz and we obtain the following values for the fit parameters:

\[
\begin{align*}
2B_0 r_0 & = 12.0(3)(7); \quad \bar{I}_3 = 3.67(12)(35); \\
f_0 r_0 & = 0.266(3)(10); \quad \bar{I}_4 = 4.69(4)(11); \quad (4.3)
\end{align*}
\]

where the renormalized quantity \( B_0 = Z_F B_0 \) is given in the \( \overline{\text{MS}} \)-scheme at the scale \( q = 2 \text{ GeV} \) (see sect. 2.2). The \( \chi^2 \)-dof of the fit is 0.28. Using the experimental input at the physical pion point we find \( r_0 = 0.433(5)(16) \text{ fm} \). Inserting the values of \( r_0 = a \) (see sect. 1.2), one gets the estimates

\[
\begin{align*}
a\beta = 4.05: & \quad 0.655(8)(24) \text{ fm}, & \quad a\beta = 3.9: & \quad 0.0830(10)(31) \text{ fm}, & \quad a\beta = 3.8: & \quad 0.0970(13)(37) \text{ fm}.
\end{align*}
\]

In the above results, except for the case of \( 2B_0 r_0 \), the second error comes entirely from the systematic uncertainty due to residual \( O(a^2) \) cutoff effects: for each quantity this error is conservatively taken as the maximum of (i) the uncertainty resulting from the propagation through the chiral analysis of the systematic error associated to the continuum estimates as derived in sect. 3.1 and (ii) the spread of the results obtained separately at \( \beta = 3.9 \) and \( \beta = 4.05 \) (by fitting to the same \( \chi \)PT ansatz as here – see sect. 4.1.3). In practice the maximum is usually given by the former of these two systematic error estimates. Note however that for \( B_0 \), \( m_{ud} \) and the chiral condensate, an additional systematic uncertainty coming from \( Z_F \) (as quoted in Ref. [5]) is added in quadrature.

As a check, we also study the decay constant \( f_{PS} \) as a function of \( m_{PS} \), i.e. with no reference to \( \mu_R \). The appropriate NLO \( \chi \)PT fit ansatz is obtained (ignoring NNLO corrections) by replacing \( 2B_0 \mu \) with \( m_{PS} \) in eq. (4.2). The resulting best fit parameters are \( f_0 r_0 = 0.268(3)(12) \) and \( \bar{I}_4 = 4.82(4)(14) \). This is consistent with the values in eq. (4.3) and yields for the Sommer scale the estimate \( r_0 = 0.435(4)(15) \text{ fm} \). The second error again comes from (the propagation of) the systematic uncertainty in the “continuum extrapolation” of sect. 3.1.
4.1.2 $\chi$PT analysis combining $\beta = 3.9$ and $4.05$

As argued in sect. 2.3, given the absence of statistically relevant cutoff effects, one can combine the data (in lattice units) for $m_{PS}$ and $f_{PS}$ coming from our simulations at $\beta = 3.9$ and $\beta = 4.05$ and perform a global combined fit based again on eqs. (4.1)–(4.2). Such a combined fit has six free parameters which can be taken as $(aB_0)_{\beta=3.9}$, $(aB_0)_{\beta=4.05}$, $(a f_0)_{\beta=3.9}$, $(a f_0)_{\beta=4.05}$, $\Lambda_3 = f_0$ and $\Lambda_4 = f_0$. Details and plots concerning this analysis can be found in Ref. [4]. The outcome is summarised in Table 1. As for the estimates of $a$, the second error we quote is an estimate (see sect. 3.1.1) of the systematic uncertainty due to residual cutoff effects. We note that, leaving out the cases for which $m_{PS} > 500$ MeV, nine ensembles of gauge configurations enter this analysis: five at $\beta = 3.9$ ($B_1$ to $B_5$) and four at $\beta = 4.05$ ($C_1$ to $C_5$).

4.1.3 Independent $\chi$PT analyses at $\beta = 3.9$ and $4.05$ and comparison

These analyses, always based on eqs. (4.1)–(4.2), are closely analogous to that presented in Ref. [1]. The free parameters can be taken to be $aB_0$, $a f_0$, $\Lambda_3 = f_0$ and $\Lambda_4 = f_0$, the best fit values of which are given in Table 1 and illustrated in Fig. 4. For the case of $\beta = 3.9$ the only difference with respect to Ref. [1] is the increased statistics and in particular the presence of the ensemble $B_6$. For both $\beta = 4.05$ and $\beta = 3.9$ the same ensembles are considered as in the case of the global combined fit of sect. 4.1.2. It should be noted that in the analysis of sect. 4.1.1 the ensembles $C_5$ and $B_6$ were not employed, in order to avoid to heavily rely on the CDH-formulae in the “continuum extrapolations” discussed in sect. 3.1.1. On the other hand using these two ensembles, in particular $B_6$ (which corresponds to $L = 2.7$ fm) increases the statistical information.

In Table 2 results from the independent analyses at $\beta = 3.9$ and $4.05$, the combined fit of sect. 4.1.2 and the fit in the continuum of sect. 4.1.1 are compared (the second error, whenever quoted, is the systematic one previously discussed). The agreement between the last two columns of Table 2 is good, even within statistical errors only. We recall that the ensembles $B_6$ and $C_5$ do not contribute to the results in the last column. Were these ensembles not used also in the combined fit of sect. 4.1.2, the results in the third column of Table 2 would get, as expected, even closer to those

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|c|}
\hline
$\beta$ & single-$\beta$ fit & single-$\beta$ fit & combined fit – see sect. 4.1.2 \\
\hline
$2aB_0$ & 4.85 (4) & 3.87 (6) & 4.87 (4) & 3.76 (3) \\
$a f_0$ & 0.9526 (4) & 0.9404 (7) & 0.9527 (4) & 0.9411 (4) \\
$\Lambda_3 = f_0$ & 6.36 (26) & 7.20 (48) & 6.41 (26) & \\
$\Lambda_4 = f_0$ & 11.59 (19) & 11.81 (31) & 11.51 (21) & \\
$\chi^2$/dof & 7.8–6 & 2.2–4 & 12.0=12 & \\
\hline
$a \mu_\pi$ & 0.00072 (2) & 0.00054 (2) & 0.00072 (1) & 0.00057 (1) \\
a [fm] & 0.6854 (6) & 0.6656 (10) & 0.6855 (5) (31) & 0.6667 (5) (24) \\
\hline
\end{tabular}
\caption{Results from $\chi$PT fits at single $\beta$-values and from the global combined fit of sect. 4.1.2.}
\end{table}

\footnote{From this analysis, without using $r_0$, we find $a \mu_{\beta=3.9} - a \mu_{\beta=4.05} = 1.28 (1)$, which is quite close to $(r_0 - a) \mu_{\beta=4.05} - (r_0 - a) \mu_{\beta=3.9} = 1.27 (1)$. Moreover, the comparison of the ratios $f_0 / B_0 \mu_{\beta=3.9}$ and $f_0 / B_0 \mu_{\beta=4.05}$ provides a rather precise estimate of the ratio $Z_F (\beta = 3.9; a \mu_{\beta=3.9} q) / Z_F (\beta = 4.05; a \mu_{\beta=4.05} q)$.}
From the fit after the continuum extrapolation we get the values of $\beta$ for the light quark mass at $\mu_R R_0$ in the continuum 

$$\beta = 4.05 \text{ and } \beta = 3.9 \text{ for (a) } r_0 m_{PS}^2 = \mu_R$$

and (b) $r_0 f_{PS}$ vs. $\mu_R r_0$ are shown, with the corresponding best fit curves to eqs. (4.1)–(4.2). The points at $\mu_R r_0 \approx 0.07$ were not included in the fit.

![Figure 4](image)

**Figure 4:** Independent $\chi$PT fits at $\beta = 4.05$ and $\beta = 3.9$: FS-corrected data above CDH for (a) $r_0 m_{PS}^2 = \mu_R$ and (b) $r_0 f_{PS}$ vs. $\mu_R r_0$. The data at $\mu_R r_0 \approx 0.07$ were not included in the fit.

| LEC | single-fit at $\beta = 3.9$ | single-fit at $\beta = 4.05$ | combined fit | fit in the continuum |
|-----|---------------------------|-----------------------------|--------------|----------------------|
| $\tilde{t}_3$ | 3 ± 4 (9) | 3 ± 6 (14) | 3 ± 4 (35) | 3 ± 6 (12) |
| $\tilde{t}_4$ | 4 ± 2 (4) | 4 ± 6 (7) | 4 ± 1 (11) | 4 ± 6 (11) |
| $2 r_0 B_0$ | 11 ± 6 (3) (5) | 11 ± 9 (3) (5) | 12 ± 6 (3) (5) | 12 ± 6 (3) (7) |
| $f_0 r_0$ | 0 ± 27 (2) | 0 ± 26 (5) | 0 ± 23 (10) | 0 ± 26 (10) |
| $r_0$ [fm] | 0 ± 46 (4) | 0 ± 34 (7) | 0 ± 44 (16) | 0 ± 33 (5) (16) |

Table 2: Estimates of LEC and $r_0$ from the analyses of sects. 4.1.3 (1st and 2nd column), 4.1.2 (3rd column) and 4.1.1 (last column). The values of $2 r_0 B_0$ are obtained using $Z_P$ at $\beta = 3.9$ [12] and $Z_P$-ratios from the analyses of sects. 4.1.2 and 4.1.1: at $\beta = 4.05$ we quote the two (similar) results obtained in this way.

in the last column: $\tilde{t}_3 = 3 ± 6 (9)$, $\tilde{t}_4 = 4 ± 6 (5)$, $2 r_0 B_0 = 11 ± 9 (3)$, $f_0 r_0 = 0 ± 270 (3)$, $r_0 = 0 ± 39 (5)$ fm.

For reviews on determinations of the LEC we refer to Refs. [13, 16].

### 4.2 Continuum estimates of $m_{ud}$ and the chiral condensate

Our preliminary results in the $\overline{\text{MS}}$-scheme at scale $q = 2$ GeV are obtained using the RI-MOM estimate [12] of $Z_P$ at $\beta = 3.9$ (converted to $\overline{\text{MS}}$ by using NNNLO perturbation theory) and the $Z_P$-ratios from the analysis of sect. 4.1.1 (combined fit) or 4.1.2 (fit in the continuum). The average light quark mass $m_{ud}$ ($\overline{\text{MS}}$; 2 GeV) from the fit in the continuum reads $m_{ud} = 3.34 (13) (23)$ MeV. From the combined fit we get $m_{ud} = 3.68 (10) (23)$ MeV (using all the ensembles) and $m_{ud} = 3.69 (13) (23)$ MeV (when excluding ensembles $B_6$ and $C_5$, i.e. with the same set of ensembles as for the fit in the continuum). When considering data at $\beta = 3.9$ only (as in sect. 4.1.3), we obtain $m_{ud} = 3.58 (13) (23)$ MeV. This value is compatible with the one coming from the partially quenched analysis of Ref. [17], $m_{ud} = 3.85 (12) (40)$ MeV.

The chiral quark condensate is obtained through $\langle \bar{q} q \rangle (\overline{\text{MS}}; 2 \text{ GeV}) = \langle 1 = 2 \rangle f_0^2 B_0 (\overline{\text{MS}}; 2 \text{ GeV})$. From the fit after the continuum extrapolation we get $\langle \bar{q} q \rangle _{\tilde{c} = 4} = 272 (4) (7)$ MeV, while from the combined fit analysis we obtain $\langle \bar{q} q \rangle _{\tilde{c} = 3} = 267 (4) (7)$ MeV (and $\langle \bar{q} q \rangle _{\tilde{c} = 3} = 270 (4) (7)$ MeV when the ensembles $B_6$ and $C_5$ are not used). These results are in agreement with an independent estimate at $\beta = 3.9$ from the $\epsilon$ regime – see Ref. [18].
5. Scaling analysis of other hadronic observables

Here we briefly report on the scaling behaviour of other hadronic observables. Even if at \( \beta = 3.8 \) preliminary data are available only for the meson vector mass and the physical volumes at the various lattice resolutions (\( L ' 2 \) fm for \( \beta = 4.05, 3.9 \) and \( L ' 2.4 \) fm for \( \beta = 3.8 \)) are only approximatively matched, this overview suggests that when employing maximally twisted Wilson quarks the cutoff effects on physical quantities are in general as small as expected on the basis of \( O(a) \) improvement.

5.1 Nucleon and vector meson masses

In Fig. 5, we show our data (in units of \( r_0 \)) for the vector meson “mass”, \( m_V \), and the nucleon mass, \( m_N \), as a function of \( m_{PS}^2 \). For the former one (see Ref. [19] for more details), the scaling appears to be good, although within statistical errors that become of few percents when \( m_{PS} \) is between 300 and 350 MeV. In this case, we remark that what we call the “mass” may differ from the actual vector meson mass (the one that becomes \( m_{\rho} \) as \( m_{PS} \rightarrow m_{\pi} \)), owing to the effect of virtual \( \rho - \pi \pi \) mixing. Due to the finite volume, the decay of the \( \rho \)-meson (at rest) into real \( \pi \pi \) states is instead forbidden, even when \( 2m_{PS} < m_V \) (which roughly speaking happens in the region \( (m_{PS}r_0)^2 > 1 \)).

The data for the nucleon mass are also preliminary (see Ref. [20]): at \( \beta = 4.05 \) only two data points are available, which however appear to agree quite well with the data points at \( \beta = 3.9 \).

5.2 Charmed observables in partially quenched setup

To compute charmed observables we adopt a partially quenched (PQ) setup, which is detailed in Ref. [21]. With the notation of Ref. [22] for valence quarks, the correlators for \( D (\bar{c}d) \) and \( D_s (\bar{c}s) \) charged mesons are computed with Wilson parameters \( r_d = r_s = r_c = 1 \), in order to have

\[ 9 \text{The correction is estimated [19] to be almost irrelevant within our present statistical errors: at our most chiral point, where } m_{PS} = 300 \text{ MeV, it amounts to } m_V - m_{\rho} \approx 0.05m_V. \]

\[ 10 \text{The proof of automatic } O(a) \text{ improvement given in Ref. [22] for a fully unquenched mixed action framework goes through also in the PQ mixed action setup of Ref. [21], where the quark masses of the valence } x \text{ and } c \text{ quarks are taken finite and hence different from those (infinite in the present case) of the corresponding sea quarks.} \]
Scaling and low energy constants in $N_f = 2$ Mtm-LQCD

Roberto Frezzotti and Gregorio Herdoiza

scaling and low energy constants in $N_f = 2$ Mtm-LQCD

Figure 6: $f_D R_0$, $f_D s R_0$ (a) and $m_D s R_0$ (b) vs. $m_D r_0$ for two lattice spacings ($\beta = 4.05$ and $3.9$) and $L = 2_{-1}^{+1}$ fm.

the same nice parametric scaling properties as in the charged pion sector. For the present considerations about scaling we choose close-to-realistic renormalization conditions: $m_{PS} r_0 = 0.7092$ and $\mu_{sp} = \mu_c = 0.082$ (instead of the realistic conditions $m_{\pi} r_0' = 0.30$ and $\mu_u = \mu_c' = 0.088$). In Figs. 3, $m_D$ varies with $\mu_c$ at fixed values of $\mu_s = \mu_c$ and $m_{PS} r_0$ (i.e. $\mu_{ud}$). The expected size of the dominating cutoff effects is $(\mu_{sp})^2 \div 0.1$, since typically, $\mu_{sp} \geq 0.030; 0.033$ and $\mu_c \geq 0.25; 0.30$.

By comparing the preliminary results from $\beta = 4.05$ and $\beta = 3.9$, we see that the observed scaling violations are not large: from $1-2\%$ (hardly visible within statistical errors) for $f_D$ and $m_D s$ to $7-8\%$ for $f_D s$. Data from a third lattice spacing, $\beta = 3.8$, are currently being analysed and may allow for an estimate of continuum limit results.

6. Conclusions and outlook

We have reported on the scaling properties of lattice QCD with $N_f = 2$ maximally twisted Wilson quarks, in the unitary \cite{4} as well as in a partially quenched setup \cite{17, 21}. Very good scaling properties are found in the light (charged) PS-meson sector and also for various charmed PS-meson observables, as well as in the vector meson and the parity-even nucleon channels, in agreement with the expectation of automatic O($a$) improvement of physical observables. Based on these findings, we presented $\chi$PT-based analyses suggesting that the determinations of the LEC’s (among which those relevant for the chiral condensate) and of the average $u,d$ quark mass that were obtained for one single lattice resolution in Refs. \cite{1, 17} are likely to be close to their continuum limit $N_f = 2$ QCD values. Moreover, combining the results presented here with those of Ref. \cite{20}, after appropriate chiral extrapolations, one finds an estimate of the ratio $m_N = f_\pi$ that is in good agreement with experiment. The framework of lattice QCD with maximally twisted Wilson quarks appears thus to offer good prospects for reliable computations of many physical QCD observables and weak matrix elements in the continuum limit.

Acknowledgements

We thank all our ETM collaborators for many important contributions to this work. In particular we are grateful to those who directly provided us with specific results: C. Alexandrou (nucleon mass), B. Blossier (charmed observables – besides a crucial contribution to the computation of $r_0$.
at $\beta = 3.8$), C. Michael (vector meson mass), V. Lubicz and S. Simula (renormalization constants). This work was partially supported by the EU Contract MRTN-CT-2006-035482 “FLAVIAnet”.
