Abstract

Background Alveolar echinococcosis (AE) is a potentially lethal zoonosis caused by the cestode Echinococcus multilocularis. The aim of this research is to investigate the dynamic changes of monocytes, macrophages and related cytokines in animal models of persistent infection of Echinococcus multilocularis, specifically exploring the possible immune changes in infection of Echinococcus multilocularis.

Methods An infection model was established by intraperitoneal injection of a protoscolex suspension. The pathological changes of mice liver were observed by HE staining and the score scale of infection was established. The ratio of Ly6C<sup>hi</sup> and Ly6C<sup>lo</sup> Monocytes in peripheral blood of mice was detected by flow cytometry. The distribution and expression of CX3CL1, CX3CR1, iNOS, CD163 and CD11b in mouse liver were detected by immunohistochemistry. The mRNA expression levels of TNF-α and Arg1 in mouse liver were detected by qRT-PCR. The expression levels of INF-γ, IL-17, IL-4 and IL-10 in peripheral blood of mice were detected by ELISA.

Results The results of HE staining showed that significant lesions appeared in the later stages of infection in the liver. The results of the infection degree score scale showed that the severity score value increased with the prolongation of the infection time. The results of flow cytometry showed that the proportion of Ly6C<sup>hi</sup> monocytes in the peripheral blood of the experimental group mice was decreased after a brief rise, Ly6C<sup>lo</sup> monocytes decreased first and then increased. The results of immunohistochemistry showed that the expression of CX3CL1, CX3CR1, CD11b, CD163 and iNOS in the mouse liver of the experimental group was increased. The results of qRT-PCR showed that the expression level of TNF-α and Arg1 mRNA in the liver of the experimental group mice increased. The results of ELISA showed that the expression level of IFN-γ, IL-17, IL-4 and IL-10 increased with the duration of infection.

Conclusions Monocytes as a supplement to hepatic macrophage, monocytes and kupffer cells (KCs) both participate in Th1 and Th2 immune responses of the body by differentiating into M1 or M2 at different stages of Echinococcus multilocularis infection.

Background

Echinococcosis refers principally to two serious zoonosis caused by Echinococcus granulosus and Echinococcus multilocularis, Cystic echinococcosis (CE), and Alveolar echinococcosis (AE). Both diseases are transmitted through ingestion of parasite eggs in the feces of the ultimate host, and humans are not necessary intermediate hosts in the life cycles of the two parasites. The life cycle of Echinococcus multilocularis takes place between canids as the definitive hosts and their prey, small mammals such as rodents, which act as intermediate hosts. Annually there are estimated more than 16,000 new cases worldwide of AE, with 90% of those occurring in China[1]. In AE patients, 98% of infections occur primarily in the liver, and the mortality rate of untreated or poorly treated patients after diagnosis is about 90% within 10 to 15 years[2].
Macrophages play a leading role in regulating liver homeostasis under physiological and pathological conditions. Resident macrophages of the liver, kupffer cells (KCs), represent a unique cell population. Most of the KCs belong to the self-sustaining macrophage cell population, whose origin is not in the bone marrow[3]. Blood monocyte-derived macrophages are a small fraction of macrophages in the liver. According to different estimates, they account for 5% to 30% of the total number of liver macrophages[4, 5]. Chemokines are cytokines with chemotaxis functions, which are specifically used to regulate the migration of immune cells into damaged or diseased organs. A variety of chemokines and receptors is expressed on the surface of monocytes and macrophages. These chemokines and receptors are involved in the migration. The CX3CL1 / CX3CR1 pathway affects the recruitment of leukocytes, include monocytes and macrophages, to target areas by affecting the expression of cytokines and chemokines in the active phase of the disease[6]. KCs and monocyte-derived macrophages play different or crucial roles in the inflammatory response caused by persistent infection of the liver[7]. Different types of macrophages synthesize and secrete cytokines such as TNF-α, IL-1β, IL-6, IL-17, IL-4, IL-12, IL-18, IL-10 and IFN-γ will increase and fully participate in the immune response when they are stimulated[3, 8, 9]. M1 and M2 phenotypes are currently considered two extremes in the type of macrophage function. M1 macrophages are generally understood to play a positive role, they are mainly involved in Th1 type immune response, promoting inflammatory response and enhancing the body's ability to kill pathogens. M2 macrophages are mainly involved in Th2 type immune response and humoral immunity, which can cause relatively weak lethality to the pathogens in the cell, and at the same time strengthen the ability to remove body residual materials and tissue repair[10, 11].

In this study, we used flow cytometry, immunohistochemistry, qRT-PCR and other methods to detect the dynamic changes of KCs and monocytes in mice during continuous infection of *Echinococcus multilocularis*. It was proved that monocyte-derived macrophages and KCs both secreted Th1 cytokines in the form of M1 to participate in the immune response in the early stage of infection, and secreted Th2 cytokines in the form of M2 to participate in the process of infection in the late stage of infection.

**Methods**

**Mice**

SPF grade Balb / c mice, female, 80, 6–8 weeks old, provided by the First Affiliated Hospital of Xinjiang Medical University Experimental Animal Science Research Department. All experimental procedures were conducted under strict guidelines and approval of Institutional Animal Use and Care Committee at Xinjiang Medical University (Approving Number: 20170214-106).

**Grouping and establishment of Echinococcus multilocularis infection model**

80 Balb / c mice were randomly divided into 2 groups, the experimental group (40) and the control group (40). 40 Balb / c mice were inoculated intraperitoneally with *Echinococcus multilocularis*, the mice was sacrificed by cervical dislocation, the vesicles fluid and the infected tissue were removed aseptically in a 50 ml syringe respectively. The tissue was ground in a sterile mortar. The ground tissue was sifted with
prepared normal saline solution containing 500 U / ml penicillin and 100 U / ml streptomycin through a 200-mesh nylon mesh. The filtrate was put into 50 ml sterile centrifuge tube to make protoscolex deposit. Finally, the sediments were resuspended in PBS to prepare the 2,000 protoscolexes / ml protoscolex suspension. The mice in experimental group were injected intraperitoneally with 1 ml of protoscolex suspension, and the mice in control group were injected intraperitoneally with the same amount of saline. They were maintained in an air-conditioned animal room with a 12-hour light/dark cycle, and provided with rodent chow and water.

**Specimen collection**

Specimens were taken and preserved 2d, 8d, 30d, 90d, 180d after infection respectively. 1000 μl blood was collected in 1.5 ml EP tube from eyes’ blood. Approximately 500 μl was transferred to a blood collection tube with EDTA-2K and awaited detections by flow cytometry. The rest was left at room temperature for 1 hour, centrifuged at 4°C, 3000 r / min for 5 min, and the upper serum obtained after centrifugation was transferred to a new EP tube. The specimens were labeled and frozen in a refrigerator at -20°C until serological detections. After the blood collection, the mice were sacrificed immediately by cervical dislocation, and then immersed in 75% alcohol for 5 min. The mice were dissected and observed for intra-abdominal infection and photographed. The liver of the mice were stripped aseptically and photographed. Part of the livers were fixed in 4% paraformaldehyde fixing solution for 7 days, waiting for subsequent histopathological and immunohistochemical staining detections. The remaining part of the liver was placed in a cryopreservation tube and frozen in liquid nitrogen immediately, then transferred to a -80°C refrigerator for storage, waiting for subsequent qRT-PCR experiments.

**Histopathological examination**

The Paraformaldehyde-fixed samples were dehydrated in ethanol, cleared with xylene and embedded in paraffin wax. Sections (4 μm thick) were prepared and stained with hematoxylin and eosin.

**Flow cytometry**

500 μl of blood was collected from mice by tube with EDTA-K2, red cells lysed using RBC lysis buffer (Biolegend, San Diego, USA), the remaining cells stained with antibodies at 4°C for 30 min., and then the cells were washed with 1% BSA wash solution. The cells were suspended in 300 μl of PBS solution and then sorted using a BD LSR II system. FITC Rat Anti-CD11b (Becton, Dickinson and Company) and PerCP-Cy™5.5 Rat Anti-Mouse Ly-6C (Becton, Dickinson and Company) were used. All the data were processed using the FlowJo (Tree Star, Ashland, OR, USA).

**Immunohistochemical detection**

The sections were routinely dewaxed to water, incubated with 3% hydrogen peroxide at room temperature for 10 min, placed in citrate buffer at 95°C for 15 min, cooled to room temperature. The sections were blocked in goat serum for 30 min and incubated overnight at 4°C with the following primary antibodies: rabbit anti-CX3CL1 (1:500, Bioss, China), rabbit anti-CX3CR1 (1:500, Bioss, China), rabbit anti-iNOS
(1:400, Bioss, China), rabbit anti-CD163 (1:500, Bioss, China) and rabbit anti-CD11b (1:4000, Abcam, USA). After being washed in PBS solution, the sections were incubated with the secondary antibodies for 1 h. The following secondary antibodies were used: goat anti-rabbit IgG HRP conjugate (ZSGB-Bio, China). After being washed in PBS solution, develop color at room temperature with DAB. The nuclei were stained with hematoxylin. Positive area were counted by an unbiased, blinded investigator using ImageJ software.

**RNA isolation and qRT-PCR**

Total RNA of liver samples was isolated using the TRIzol reagent (Invitrogen, USA) according to the manufacturer's instructions and reverse transcribed using Prime Script RT Master Mix (RR036A, Takara, Japan). Real-time PCR was performed using SYBR Premix Ex Taq II (RR820A, Takara, Japan) in Thermal Cycler Dice™ Real Time System II (BIO-RAD, IQ5, USA). All PCRs were performed at least twice. The comparative method of relative quantification ($2^{\Delta\Delta C_{t}}$) was used to calculate the expression level of the target gene normalised to the housekeeping gene glyceraldehyde-3-phosphate dehydrogenase (GAPDH). The primers used for qRT-PCR were listed in Table 1.

| Table 1 qRT-PCR using gene primers |
|-----------------------------------|
| **Gene** | **Primers (5’→3’)** |
|---|---|
| TNF-α | Forward: CCCCTTTATCGTCTACTCCTC  
Reverse: GCTGGTAGTTAGCTCCGTTT |
| Arg1 | Forward: CTCCAAGCCAAGTCCTAGAG  
Reverse: AGGAGCTGTCATTAGGGACATC |
| GAPDH | Forward: AACTTTGGCATTGTGGAAGG  
Reverse: CACATTGGGGGTAGGAACAC |

**ELISA for quantitative detection of INF-γ and other cytokines**

50 μl samples (serum) and diluted standards were added into wells, and then, 50 μl of biotin conjugate was added into each well. The plates were covered with adhesive film and incubated at room temperature for 2 h on a microplate shaker. Then, the wells were washed six times with wash buffer. Next, 100 μl of diluted streptavidin-HRP was added to wells and then incubated at room temperature for 1 h. After six washes, 100 μl of TMB substrate solution was added into each well, incubated at room temperature for 30 min, and then stop solution was added. The optical density in each well was measured by microplate reader (Multiskan Spectrum, Thermo Scientific, USA). Cytokine concentrations were calculated by referring to standard curves.

**Statistical Analysis**
Results were analyzed using SPSS software (version 17). Comparisons between groups were made using chi-square test / one way ANOVA. Differences were considered significant when $P \leq 0.05$.

Results

General condition of mice

With the prolongation of the feeding time, the weight of the two groups of mice showed an increasing trend, but the increase in the experimental group was more significant (Table 2). The mice of control group showed no abnormal changes in the liver and abdominal cavity after dissection. The liver texture was soft, smooth, ruddy in color without obvious adhesion. The anatomical position was normal. After dissecting the mice in the experimental group, it was found that as the infection continued, the liver of the mice gradually hardened, the color gradually faded, and the anatomical position gradually deviated from the normal anatomical position. At 30d after infection, the vesicles were seen on the liver, then the vesicles gradually increased. The boundary between vesicles and tissue was blurred. The vesicles were also formed in the abdominal cavity. At the late infection, abdominal cavity was almost full of vesicles (Fig.1, Fig.2).

| Days after infection (d) | n | Weight (g) |  |
|-------------------------|---|------------|---|
|                         |   | Control group | Experimental group |
| 2                       | 8 | 21.52±0.65 | 21.09±1.01   |
| 8                       | 8 | 21.82±0.77 | 21.93±0.85   |
| 30                      | 8 | 23.65±0.58 | 24.71±1.03   |
| 90                      | 8 | 24.88±0.44 | 30.23±2.39*  |
| 180                     | 8 | 30.46±1.00 | 37.56±3.36** |

Note: The experimental group was compared with the control group at the same period * $P \leq 0.05$, ** $P \leq 0.01$

Histological analysis of the liver tissue

The control group’s mice in all periods had normal liver tissue structure and complete hepatic lobules. Hepatocytes were arranged neatly with clear and complete borders. There was no edema, necrosis, and ballooning degeneration in liver cell. After observing the mice in experimental group, we found that as the infection continued, the hepatocytes gradually developed from initial edema to ballooning degeneration and steatosis. At 8d of infection, the mild inflammation in the portal area began to appear, and it became worse with the prolongation of the infection time. At the same time, a small number of focal necrosis could be seen in the hepatic lobules. With the prolongation of infection time, it gradually increased,
developed into fusion necrosis or bridging necrosis and involved many hepatic lobules. In the late stage of infection, a large number of fibroblasts around the lesion proliferated to form a fibrous layer, and a large number of inflammatory cells infiltrated. Normal hepatic lobule structures were no longer visible (Fig.3).

According to the pathological changes in HE stained hepatic lobules of liver tissue of mice infected with *Echinococcus multilocularis*, lesions in the manifold area, other abnormal structures and substances, combined with chronic hepatitis GS classification, a score scale for the degree of *Echinococcus multilocularis* infection in mice (Table 3). Tissue samples scored according to Table 3. After summing up the scores, the higher the score, the severer the infection. (Fig.4).

| Degree of inflammation | Vesicles*  | Abnormal structures and substances | Score |
|------------------------|------------|-----------------------------------|-------|
| Hepatic lobule         | Portal area and surrounding |                     |       |
| No inflammation        | No inflammation          | 0                   | No obvious change 0 |
| Degeneration, small amount spotted and focal necrosis | Mild inflammation (Inflammatory cells occupy less than 1/3 of the portal area) | 1-3 | Granuloma 1 |
| Degeneration, large amount spotted and focal necrosis | 4-6 | 2 |
| Confluent necrosis or bridging necrosis | Moderate inflammation (Inflammatory cells occupy 1/3~2/3 of the portal area) | 7-9 | Laminated layer and germinal layer 3 |
| Extensive bridging of necrosis and involved many hepatic lobules | Severe inflammation (Inflammatory cells occupy more than 2/3 of the portal area) | ≥10 | Brood capsule and protoscolex 4 |

* Note: the average number of vesicle counts was observed in at least 3 different fields under low power microscope (magnification, ×100).

**Detection results of monocyte subsets in peripheral blood**
Ly6C is currently the most ideal marker for distinguishing monocyte subpopulations in mice[12]. Then we used flow cytometry to detect the proportion of monocyte subsets in the peripheral blood of mice in control and experimental groups in different periods. We found that a little change in the proportion of two kinds of monocytes in mice of control group. In experimental group, the proportion of Ly6C\textsuperscript{hi} type monocytes gradually increased in the early stage of infection, reached a peak at 8d after infection. Then it began to show a downward trend. At the later stage of infection, it had been significantly lower than the control group at the same time (Fig.5 G). For Ly6C\textsuperscript{lo} type monocytes, its proportion rapidly decreases to a minimum after a brief rise in the early stages of infection. Then its proportion began to rise, and at the later stage of the infection, its proportion was already significantly larger than that of the control group during the same period (Fig.5 H). The above results showed that in the continuous infection of *Echinococcus multilocularis*, the mainly monocyte subsets in peripheral blood transited from Ly6C\textsuperscript{hi} to Ly6C\textsuperscript{lo}.

**Immunohistochemical results of liver tissue of *Echinococcus multilocularis* infection mice**

Earlier, we have observed changes in the proportion of peripheral blood mononuclear cell subsets in infected mice. So did these cells reach the lesion? Subsequently, we used immunohistochemistry to detect monocyte markers, CD11b, related chemokines and their receptors CX3CL1 and CX3CR1, different types of macrophages markers, iNOS and CD163. The results showed that all indicators were low and stable in the control group. The expression of chemokine CX3CL1 increased with the prolongation of the infection time. Although the expression level decreased in the late stage of infection, it remained at a high level (Fig.7 A). Most of its expression locations were concentrated in inflammatory cell clusters or around lesions. CX3CR1 had a higher expression level than control group at the early stage of infection. Although the expression level decreased briefly at 30d after infection, it was still significantly higher than that of control group in the later period (Fig.7 B). The location of its expression gradually concentrated around the lesion with the prolongation of the infection time. For CD11b, its expression increased with the prolongation of infection time (Fig.7 C), and almost all of the expression sites were at the inflammatory cell aggregation site. The expression of iNOS that one of the markers of M1 macrophages, increased with the prolongation of the infection time, but the expression level in the late stage of infection was no longer than the intermediate stage (Fig.7 D). CD163 is one of the markers of M2 macrophages. And its expression also increased with the prolongation of infection time. The expression of CD163 in the late stage of infection was the highest during the entire infection process which is unlike iNOS (Fig.6, Fig.7 E). In summary, our results illustrate the following conclusion, under the role of chemokines and their receptors, monocytes expressing CD11b were recruited into the liver and concentrated around the lesion at the late stage of infection. Macrophages around the lesion were predominantly M1 and M2 in the early and late stages of infection, respectively.

**Detection of different subsets macrophage related genes**

After that, in order to verify the previous conclusions, we carried out the detections of liver macrophage-related gene. The results of qRT-PCR showed that TNF-\(\alpha\), a marker gene of M1 macrophages, began to
increase significantly at 30d after infection. Its expression reached its peak at 90d. Although it decreased
in the late period, it was still significantly higher than the control group in the same period (Fig.8 A). Arg1,
one of the marker genes of M2 macrophages, also began to increase significantly at 30d after infection.
But the difference was that it reached a peak in the late stage of infection with the prolongation of the
infection time (Fig.8 B). The experimental results supported our previous conclusions that macrophages
in the liver underwent a continuous transition from M1 to M2 in the continuous infection of *Echinococcus
multilocularis*. So, how do these macrophages that have been polarized participate in the mice's immune
response at different stages of continuous infection in *Echinococcus multilocularis*?

**Results of detection of macrophages related cytokines**

In order to explore the immune function of macrophages that have been polarized at different stages of
infection, we detected several cytokines associated with different types of macrophages. First, we
detected changes in the expression of IFN-γ in peripheral blood. Its expression trend was similar to that of
M1-type macrophages (Fig.9 A). Both of them increase with the duration of infection, and begin to decline
in the later stages of infection. Then, we detected changes in the expression of IL-17. During the entire
infection process, its expression continued to increase with the prolongation of the infection time,
reached a peak in the late stage (Fig.9 B). Finally, we continuously detected two cytokines, IL-4 and IL-10,
and their expression trends were similar. When the infection progressed to 90d, their expression reached a
peak and gradually decreased in the late stage of infection. The difference was that IL-10 was
significantly higher than the control group at 30d after infection, but IL-4 was not (Fig.9 C, D). This was
the difference between the two cytokines. Our results indicate that in the early stage of persistent
infection with *Echinococcus multilocularis* infection, Th1 immune response represented by IFN-γ may
play a major and important role. In the late stage of infection, maybe Th2 cytokines with higher
expression were playing a major role. Therefore, no matter in the early or late stage of infection,
macrophages of different subsets participated in the mice's immune regulation by synthesizing and
secreting relevant cytokines, and played an indispensable role.

**Discussion**

Echinococcosis is a zoonosis caused by cestodes of the genus *Echinococcus* (family Taeniidae). This
serious and near-cosmopolitan disease continues to be a significant public health issue, with western
China being the area of highest endemi city for AE[13]. The onset of AE is hidden, with a long course, with
only atypical signs such as abdominal distension, abdominal pain, loss of appetite, and weight loss.
When *Echinococcus multilocularis* resides in the liver for a certain period of time, it can have a direct
effect on the liver. It can cause an immune response to the liver and surrounding tissues through
mechanical compression and continuous overflow of small vesicle fluids. In severe cases can cause
hepatic encephalopathy or portal hypertension[14, 15]. Although the outcomes of AE patients include the
above, they are not the only ones. In clinically inactive AE patients, the lesions were prone to deposit
calcium salts, forming irregular liquefied necrotic lesions, with a milder degree, and the phenomenon of
self-healing may occur. In active AE patients, the lesions gradually increase in the liver and spread by
invasive growth. Not only are the surrounding tissues easy to be invaded, but also extrahepatic metastases or intra-abdominal vesicular bulbous plantar metastasis can be difficult to cure. As a result, local recurrence or secondary infections often occur. The difference in the host’s different immune states is an important factor influencing different outcomes. Therefore, in actual clinical work, the main direction is still to adjust the host’s immune status in a timely manner, thereby affecting or even changing the occurrence and development of the disease.

As an important part of the body’s immune defense mechanism, the function and phenotype of macrophages are highly heterogeneous, depending on its source and type of polarization. It has been reported that bone marrow-derived macrophages adapt to the needs and burdens of the liver under inflammatory conditions, while kupffer cells, liver macrophages that reside in tissues, adapt to the normal function of the liver[16]. So, how do monocytes in peripheral blood participate in the immune response? When the liver is damaged, KCs and other liver intrinsic cells will recruit a large number of mature monocyte in the blood circulation to migrate to the damaged site through the action of chemokines and their receptors, and differentiate into different types of macrophages according to different liver microenvironments. For example, the expression of Ly6C<sup>lo</sup> in recovery macrophages observed during the resolution of mice liver fibrosis were derived from Ly6C<sup>hi</sup> peripheral blood monocytes and had the characteristics of M1 and M2 macrophages[17]. Monocyte-derived macrophages will differentiate into the types that plays a positive role in the inflammatory response and aggravates liver damage. At the same time, they will also develop toward a phenotype that promotes tissue repair after liver damage. After selective depletion of KCs with clodronate liposomes or inhibition of monocyte infiltration with CCR2<sup>-/-</sup> mice, KCs and inflammatory Ly6C<sup>hi</sup> monocytes were found to aggravate amoebic liver abscess[18]. In inflammatory response syndrome of liver injury caused by African trypanosome infection, Ly6C<sup>lo</sup> macrophages can inhibit the pro-inflammatory function of Ly6C<sup>hi</sup> monocytes, and differentiate Ly6C<sup>hi</sup> monocytes into anti-inflammatory macrophages[19]. But the similar results have not been reported in AE. Therefore, we conducted related research.

In this study, mice were injected intraperitoneally with protoscolexes to make a model. After the mice were sacrificed, the infection situation in the abdominal cavity of the mice was first observed. We found that with the prolongation of the modeling time, the number and volume of vesicles scattered in the abdominal cavity of mice and the liver increased, the amount of sac fluid increased, the adhesion of vesicles to surrounding tissues gradually increased. Squeezing of giant vesicles disengages the tissue from its normal position and affects its normal function. The results of HE staining showed that with the progress of <i>Echinococcus multilocularis</i> infection, the initial focal necrosis in the hepatic lobules gradually developed into fusion or even bridging necrosis. The infiltration of inflammatory cells in the mesial area gradually worsened, and in the late stage of infection, no obvious hepatic lobular structure has been seen, and even part of the lobular structure has disappeared. After that, the infection status of the liver tissues of mice infected with <i>Echinococcus multilocularis</i> was scored, and the results showed that the total score increased with the prolongation of the infection time. However, the scoring criteria used in this study are semi-quantitative rather than quantitative. The scores represent only the type of
certain pathological patterns and are not true measurements. Therefore, different observers use the same scoring criteria can lead to different conclusions because of their experience or differences in prejudice. Therefore a more detailed description of the histological morphology can help improve the scoring criteria to play a more detailed role.

After determining the infection status of the mice, we immediately detected the change in the proportion of monocytes in different subpopulations of peripheral blood by flow cytometry. The results showed that the monocytes in the peripheral blood in the early stage of infection were mainly Ly6C^{hi} type, but in the late stage, they were mainly Ly6C^{lo} type. These monocytes which differentiate into different subsets at different times, were affected by chemokines and their receptors. And they were recruited around the lesions of liver tissue. KCs and these monocytes were recruited to the liver mainly exerted their immune function in the form of M1 macrophages in the early stages of infection, but in the later stages, most of them had differentiated into M2 macrophages that involved in subsequent immune responses. But there is an interesting phenomenon in our results, the expression trends of chemokines and their receptors are not exactly same. The reason may be that the two indicators at different stages of infection is caused by the expression of different positive cells. First, CX3CL1 has two types: soluble and bound. Second, CX3CL1 positive cells include not only monocytes and macrophages, but also myofibroblasts and endothelial cells. However CX3CR1 positive cells in mouse liver are mainly macrophages[20].

The results of immunohistochemistry and qRT-PCR of our detections on macrophages in different subsets indicate that in the early stage of *Echinococcus multilocularis* infection, macrophages in the liver will mostly participate in the development of the disease in the form of M1. In the late stage of infection, the differentiation direction of liver macrophages is mainly M2 type. There are evidences that Ly6C^{hi} monocytes can be differentiated into M1 macrophages and Ly6C^{lo} monocytes can be differentiated into M2 macrophages[21], the results of peripheral blood flow cytometry in this study also supported this phenomenon. Therefore, in combination with the previous results of this study, we have reason to believe that in the early stage of *Echinococcus multilocularis* infection, a large number of Ly6C^{hi} monocytes in peripheral blood were recruited to the liver, and played an immune role in the form of M1 macrophages together with KCs. In the late stage of infection, a predominant number of Ly6C^{lo} monocytes were recruited into the liver tissue, and it acted as M2 macrophages together with KCs.

Finally, we preliminary explored how different subsets of macrophages are involved in the entire process of *Echinococcus multilocularis* infection. We selected several cytokines synthesized by macrophages, IFN-γ, IL-17, IL-4, IL-10. IFN-γ was one of the most representative cytokines of Th1 immune response. In contrast, as the most effective antagonist of IFN-γ, IL-4 was also selected by us. Then we added one of the representative factors of Th2 immune response, IL-10. IL-17 was chosen because it was a recently discovered new type of pro-inflammatory cytokine. The change in IFN-γ in the serum of the experimental group mice further proved that during the process of *Echinococcus multilocularis* infection, the body’s immune type trend is dominated by the early Th1 and gradually transitions to the late Th2 which plays the main function. When the early expression of IFN-γ is increased, KCs can be activated to promote them
to inflammatory sites or pathogenic sites, upregulate the secretion of inflammatory molecules, and enhance the inflammatory response[22]. However, when Th1 type immune cells had an excessively strong inflammatory response, a higher concentration of IFN-γ could induct CD4+ CD25+ T cells to differentiate into CD4+ CD25+ Tregs, to inhibit the inflammatory response of disorders and reduce body damage[23]. This may be the reason why IFN-γ is still maintained at a higher concentration in the late stage of infection. Throughout the infection process, IL-17 had maintained an upward trend. In the early stages of infection, it may be due to its synergy with other pro-inflammatory cytokines such as IFN-γ. However, at the late stage of infection, high levels of IL-17 may be closely related to liver fibrosis and cirrhosis that during chronic liver disease[24]. IL-4, as an important anti-inflammatory factor, can down-regulate the effects of IFN-γ on pathogen killing and tissue damage. And it can down-regulate the secretion of Th1 cytokines, inhibit Th1 type immune function, strengthen Th2 cytokine expression to promote the formation of immune tolerance. This is why high concentrations of IL-4 appear and produce effects in the later stages of infection[25]. As one of the cytokines overexpressed by M2 macrophages, IL-10 also has a higher concentration in the late stage of infection. Although high concentrations of IL-10 helped to suppress inflammatory reactions and repair damaged tissues, they also promoted the formation of immune tolerance in the body and helped pathogens escape the body's immune response[26, 27].

*Echinococcus multilocularis* infection was a long process, and as the prolongation of infection it became a chronic disease gradually, the treatment method would become single, the disease would easily recur, and it would be difficult to cure completely. Therefore, finding a way to prevent chronic infection will be a feasible idea for treating AE. The immune tolerance mechanism formed by the body at the late stage of infection is closely related to the long-term coexistence of *Echinococcus multilocularis* and host. The imbalance of cellular immunity and humoral immunity caused by the imbalance of Th1 and Th2 is one of vital importance role in this progress. Due to the strong plasticity and functional heterogeneity of macrophages, monocyte-derived macrophages and KCs were keeping to participate in the development of Th1 and Th2 immune functions at the same time. However, there were no clear conclusions about specific functions and mechanisms. Just like we don't know what kind of cell mainly produces which kind of cytokine. But we have reasons to believe that in the future, monocyte-derived macrophages to supplement depleted KCs to help to treat AE will be a feasible idea.

**Conclusions**

In a summary, our research indicate that monocytes as a supplement to hepatic macrophage, it and kupffer cells (KCs) participate in Th1 and Th2 immune responses of the body by differentiating into M1 or M2 at different stages of *Echinococcus multilocularis* infection.

**Abbreviations**

AE: Alveolar echinococcosis; HE: Hematoxylin-eosin; qRT-PCR: Quantitative real time polymerase chain reaction; TNF-α: Tumor necrosis factor α; Arg1: Arginase-1; ELISA: Enzyme linked immunosorbent assay;
IFN-γ: Interferon-γ; IL-17: Interleukin-17; IL-4: Interleukin-4; IL-10: Interleukin-10; KCs: Kupffer cells; CE: Cystic echinococcosis;

Authors' contributions

Prof. MXM and LL conceived and designed the study. LB and QXW drafted the manuscript, MXM and LB critically revised manuscript. LB, LYM, YY, SJY, CXL, conducted experimental work. QXW, LJ, ZX interpreted data. All the authors read and approved the final manuscript.

Funding

This work was supported by the National Natural Science Foundation (81760372; 81260253; 31160194)‡ Scientific Research Project of Science Department of Xinjiang Autonomous Region (2017D01C313) and State Key Laboratory of Pathogenesis, Prevention and Treatment of High Incidence Diseases in Central Asia Fund (SKL-HIDCA-2018-27‡SKL-HIDCA-2019-10). The funding bodies had no role in the design of the study and collection, analysis, and interpretation of data and in writing the manuscript.

Availability of data and materials

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Ethics approval and consent to participate

All experimental procedures were conducted under strict guidelines and approval of Institutional Animal Use and Care Committee at Xinjiang Medical University (Approving Number: 20170214-106).

Consent for publication

Not applicable.

Competing interests

The authors declare that they have no competing interests.
