Streptococcus suis is a major pathogen in pigs and an emerging zoonotic agent (1–4). This bacterium is a natural inhabitant of the upper respiratory tract of pigs and is endemic to all pig-production countries. In pigs, S. suis causes meningitis, septicemia, polyserositis, arthritis, and endocarditis, mainly during the postweaning period; it is a source of concern for farmers because of potential economic losses and its effects on the welfare of infected pigs (2). Human infection is acquired through occupational contact or ingestion of undercooked pork-derived products and is associated with meningitis, endocarditis, septicemia, deafness, and death (5).

S. suis is a heterogeneous species. Until 2005, S. suis was divided into 35 serotypes (1–34 and 1/2), based on capsular polysaccharides, but 6 serotypes were recently reclassified as belonging to other Streptococcus species, leaving 29 currently recognized S. suis serotypes (6,7). Most S. suis infections in humans and pigs are caused by serotype 2, but the predominant serotypes causing invasive disease in pigs vary according to time and region (8). In some countries in Europe, serotype 9 has emerged as the leading cause of invasive diseases in pigs (2,8–10); prevalence of this serotype has also recently increased in China (5).

Since 2002, the introduction of a standard multilocus sequence typing (MLST) scheme has improved the description of the epidemiology of S. suis infection (8). Sequence types (STs), determined by MLST, are also better predictors of the pathogenicity of a particular isolate than are serotypes (11). Among serotype 2 isolates from pigs, ST1, a highly successful clone associated with most human infections globally, is prevalent in Europe (8). Another sequence type of serotype 2, ST7, was responsible for major S. suis epidemics among humans in 1998 and 2005 in China (12). Serotypes other than 2 are less frequently responsible for human infections (8). Of note, despite the increased frequency of pig infections caused by serotype 9, the first human case of serotype 9 infection was documented in Thailand in 2015 (13). That strain was assigned to ST16, an emerging sequence type known for its increased virulence potential and predominance in invasive S. suis infections in pigs in the Netherlands (14).
On-farm management options for controlling *S. suis* infections include improving environmental conditions (e.g., providing correct temperature, providing correct air humidity, and reducing overcrowding and pig mixing) (15). The control of viral infections, particularly porcine reproductive and respiratory virus, is also essential because they are well-known predisposing factors for the disease (16). Another tool for protecting against infection is vaccination, but available vaccines are based on bacterins and provide only nonheterologous protection (17). Thus, in many countries in Europe, including Italy, control of *S. suis* infections in pigs is based mainly on antimicrobial treatment (18). *S. suis* is generally susceptible to β-lactams, the main class of antimicrobials administered to control the infection on pig farms. Conversely, *S. suis* is almost always resistant to tetracycline; macrolide-lincosamide-streptogramin B; and, less frequently, aminoglycosides, chloramphenicol, vancomycin, and linezolid (15). In *S. suis*, genes encoding antimicrobial resistance (AMR) are often carried on mobile genetic elements that can be transferred to other members of the genus, including human pathogens (4,19). Thus, *S. suis* can be considered a public health concern because of its zoonotic potential (a leading cause of antimicrobial drug use in pig farming) and a reservoir of AMR genes (4,19).

Information about circulating strains is lacking in many countries, including Italy, which is one of the most prominent pig-production countries in Europe (8). We characterized the serotypes, sequence types, and antimicrobial susceptibility of 78 *S. suis* isolates from infected pigs in Italy. By providing updated epidemiologic information about *S. suis* infection, we aim to drive the use of autogenous vaccines, reduce antibiotic consumption, and protect animal health. We also assessed presence of *S. suis* clones with zoonotic potential.

### Materials and Methods

**Bacterial Isolates**

We investigated isolates collected from pigs with clinical *S. suis* infection on pig farms in northern/central Italy during 2017–2019. To avoid redundancy, we included only 1 isolate per year and farm. A total of 78 *S. suis* isolates were collected from piglets with meningitis (49), pericarditis (3), arthritis (3), septicemia (17), and pneumonia (8) (Appendix 1, https://wwwnc.cdc.gov/EID/article/28/1/21-0816-App1.xlsx).

The samples were cultured on 5% sheep blood agar (Biolife Italiana Srl, http://www.biolifeit.com) at 5% CO₂, 37°C, for 24–48 h. We used matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (Bruker Daltonics GmbH, https://www.bruker.com) and PCR to confirm selected suspected α-hemolytic colonies as belonging to the *S. suis* species (20).

**Antimicrobial Susceptibility Testing**

We assessed MICs by using a commercially prepared microtiter MIC panel (BOP06F, Sensititre; Trek Diagnostic Systems Inc., https://www.thermofisher.com) according to the manufacturer’s instructions and by using *Streptococcus pneumoniae* ATCC 49619 as a quality control strain. We interpreted MIC results by using the breakpoints recommended by the Clinical Laboratory Standards Institute (24) for swine respiratory *S. suis*. The interpretative criteria for trimethoprim/sulfamethoxazole and clindamycin were those recommended for human *S. pneumoniae* (25).

**Whole-Genome Sequencing**

We prepared genomic DNA from all 78 *S. suis* isolates. We extracted pure cultures from 1 mL of logarithmic-phase broth cultures by using QIAamp DNA Mini Kit (QIAGEN, https://www.qiagen.com) according to the manufacturer’s instructions and then quantified the DNA by using the Qubit fluorometer (Thermo Fisher Scientific, https://www.thermofisher.com). We assessed MICs by using a commercially prepared microtiter MIC panel (BOP06F, Sensititre; Trek Diagnostic Systems Inc., https://www.thermofisher.com) according to the manufacturer’s instructions and by using *Streptococcus pneumoniae* ATCC 49619 as a quality control strain. We interpreted MIC results by using the breakpoints recommended by the Clinical Laboratory Standards Institute (24) for swine respiratory *S. suis*. The interpretative criteria for trimethoprim/sulfamethoxazole and clindamycin were those recommended for human *S. pneumoniae* (25).

**Sequence Analyses**

Raw data were checked for quality, trimmed by using Trimmomatic version 0.36 (26), and assembled by using SPAdes genome assembler version 3.11.1 (27). To determine distinct sequence types, we performed MLST. The allele sequences and profiles were obtained from the *S. suis* MLST database (https://pubmlst.org/sssuis). We uploaded sequences for new MLST allele variations to the same database for assignment of allele identification and then uploaded final allele combinations for assignment of new
MLSTs. We submitted the raw sequencing data to the National Center for Biotechnology Information Sequence Read Archive repository (BioProject PRJNA717238, Biosample SUB9357225; accession nos. SAMN18490763–SAMN18490790).

To identify potential clonal complexes and founders, we performed global optimal eBURST (http://www.phyloviz.net/goeburst analysis). The entire S. suis MLST database was displayed as a single goeBURST diagram by setting the double-locus variants level and the group definition to 0 of 7 shared alleles. We conducted minimum core-genome sequence typing in silico (28).

We annotated genomes by using Prokka (https://github.com) and constructed a maximum-likelihood phylogenetic tree, based on the final alignment of core genome from Roary analysis, by using FastTree 2.1.11 (29). Manual annotation of the tree was performed in iTOL (v.5.7) (30). We identified AMR genes by using ARBicrate (https://github.com) against the following databases: AMRFinderPlus, CARD, RESfinder, ARG-ANNOT (31–34).

To research putative virulence genes, we created a database containing 91 previously described genes (2,3) (Appendix 2 Table 1) and searched by using BLASTN version 2.5.0+ (35). According to O’Dea et al., (17), only genes with ≥95% coverage and ≥99% identity were considered present. We investigated the null hypothesis of a random distribution of the number of virulence factors among the different sequence types and excluded sequence types represented by a small set of isolates (≤3), resulting in 8 sequence types and 65 isolates. To show the distribution of the putative virulence genes across the sequence types, we selected the putative virulence genes that were present in <90% or in >10% of isolates. After checking the normality of the data by using the Shapiro-Wilk normality test, we performed Kruskal-Wallis ranksum testing, followed by pairwise comparisons using the Dunn test for multiple comparisons of independent samples. To investigate the distribution of genes encoding putative virulence factors, we constructed a heat map based on the distance metric “euclidean” and complete linkage method. We performed all analyses in R (36).

Results

Molecular Serotyping, Virulence Genotyping, and MLST

We identified 13 serotypes: 1, 2, 1/2, 3, 4, 5, 7, 8, 9, 10, 15, 19, and 23. The most prevalent were serotypes 9, accounting for 34.6% (n = 27) of isolates, and 1/2, accounting for 25.6% (n = 20) of isolates. These serotypes were followed by 10 (n = 7, 9.0%), 2 (n = 7, 9.0%), and 7 (n = 6, 7.7%) (Table 1).

MLST analysis revealed that 59 (75.6%) isolates belonged to 9 sequence types (ST1, ST7, ST11, ST16, ST28, ST29, ST94, ST108, and ST123) in the S. suis

### Table 1. Combination of putative virulence genes among sequence types and minimum core genome groups of Streptococcus suis from diseased pigs, Italy, 2017–2019*

| Sequence type | MCG group | Serotype | Virulence profile | No. isolates/total no. isolates for each sequence type (%) |

Clinical resistance, according to 142 Emerging Infectious Diseases • www.cdc.gov/eid • Vol. 28, No. 1, January 2022

Outbreaks of meningitis, 6 of which occurred in the isolates. The serotype SS10 isolates were derived from 9, 15, and 19; the second group included serotype 10. Two sister groups: the first group comprised serotypes belonging to serotypes 8 and 9. Cluster 3 recognized relationships among the 4 isolates of the second cluster, different regions and body sites. We found no relatedness among the 4 isolates of the second cluster, belonging to serotypes 8 and 9. Cluster 3 recognized 2 sister groups: the first group comprised serotypes 9, 15, and 19; the second group included serotype 10 isolates. The serotype SS10 isolates were derived from 7 outbreaks of meningitis, 6 of which occurred in the Piedmont region of northern Italy in 2018. The fourth cluster included the highest number of isolates from our collection, belonging to 6 serotypes. We found no correlations with geographic location, year, or site of origin for members of this cluster. All penicillin-resistant SS9 isolates were grouped within this cluster (Figure 1). goeBurst analysis (http://www.phylotinf.net/goeburst) showed 5 major clusters. ST1543 and ST1544 were related to the ST19 subgroup, ST1546 to the ST1521 subgroup, and ST1545 to clonal complex (CC) 1; the other sequence types occurred as singletons (Appendix 2 Figure 1).

AMR Phenotypes and Genotypes
A total of 7 (9.0%) S. suis isolates were resistant to antimicrobial drugs, usually tetracycline (6/7) (Table 2). Most (48/78, 61.5%) isolates were resistant to 2 antimicrobials, generally (45/48) clindamycin and tetracycline. Of the 78 isolates, 23 (29.5%) were resistant to ≥3 antimicrobials and were classified as multiresistant. Multiresistance was detected in 4/17 (23%) ST1, 1/9 (11%) ST7, and 12/17 (71%) ST123 isolates. Of 17 ST123 isolates, 14 (82%) were resistant to penicillin. Multiresistance was detected in 4/17 (23%) ST1, 1/9 (11%) ST7, and 12/17 (71%) ST123 isolates. Of 17 ST123 isolates, 14 (82%) were resistant to penicillin (Tables 1, 3; Figure 1).

Phylogenetic Analyses
A total of 1,156 genes, corresponding to 19.88% of the pangenome (Appendix 2), comprised the core genome. Phylogenetic analysis of the collected isolates showed 4 major clusters and 2 singletons. The first cluster was composed of serotypes 1, 1/2, and 2 isolates and was characterized by low heterogeneity, even though these isolates originated from different regions and body sites. We found no relationship among the 4 isolates of the second cluster, belonging to serotypes 8 and 9. Cluster 3 recognized 2 sister groups: the first group comprised serotypes 9, 15, and 19; the second group included serotype 10 isolates. The serotype SS10 isolates were derived from 7 outbreaks of meningitis, 6 of which occurred in the

characterized by the presence of another group of 12 putative virulence genes related to adhesion (murM) or involved in metabolic pathways (htpSC, ppc, troA, pyrF, nox, purD, msmK, gloA, rgg, and yhbU_2, lysM) (Appendix 2 Figure 3).

**Discussion**

Among 78 S. suis isolates from diseased pigs in Italy, we identified the major serotypes associated with S. suis infections as serotypes 9 and SS1/2, responsible for almost 60% of cases. Previous studies in Italy have shown a predominance of serotype 2 infections, which were a minority in our study (1,37). Until 2020, PCR testing for serotyping did not differentiate serotype 2 from serotype 1/2, and many studies reported a difference in the number of putative virulence factors in ST7 and ST1 isolates than in other STs in our collection (39). This cluster was composed of ST1 and, unexpectedly, ST7, which is a subgroup founder related to CC1. However, such distinction is relevant because serotype 1/2 is associated with pig infections; however, different from serotype 2, its role as a zoonotic agent is still uncertain (38). With this study, we confirmed increased serotype 9 infections at pig farms, which has already been described for other countries in Europe (10). The proportion of isolates belonging to serotype 7, the third most common serotype, remained more or less stable compared with data from 2000, thus confirming the trend observed in Germany (7,37). We also detected serotypes 10 and 15 in our collection. These serotypes have not previously been detected in Italy but have been identified in Spain and the United Kingdom (37). Given the variability of serotypes and the low prevalence of serotype 2 observed in our study, complete characterization of isolates is essential for the successful implementation of autogenous vaccines. Indeed, autogenous vaccines are well-established tools for preventing serotype 2 infections, but data about their efficacy for other serotypes, including 1/2, are still lacking (16).

All serotype 2 and 1/2 isolates, except 1, were confined to a single cluster of the phylogenetic tree. This cluster was composed of ST1 and, unexpectedly, ST7, which is a subgroup founder related to CC1. The number of putative virulence factors was higher in ST7 and ST1 isolates than in other STs in our collection, which was expected, because ST1 is the predominant sequence type associated with invasive infections in pigs in Europe. Cases of S. suis infection in humans in Italy are sporadic and are caused by serotype 2, ST1 (1,39). ST7, which differs from ST1 at a single locus, has not been detected in pigs in Europe (8). However, ST7 isolates are prevalent among diseased pigs in China (40–42). The epidemic strain ST7, which is characterized by the presence of an 89-kb pathogenicity island, the insertion of a 128-kb ICE (integrative and conjugative element)–phage tandem mobile genetic element, is responsible for the 2 largest outbreaks of human S. suis infection, which occurred in 1998 and 2005 (42). The ST7 isolates from our study lacked the virulence genes harbored by the 89-kb pathogenicity island; thus, their zoonotic potential may be lower than that of the ST7 epidemic strain in China. Moreover, they did not cluster with the newly described lineage III of ST7 (Appendix 2 Tables 2–4, Figure 2) (43). Further analysis is necessary to explain the presence of ST7 in Italy. New S. suis strains may

### Table 3. Antimicrobial resistance genes identified in the 78 Streptococcus suis isolates from diseased pigs, Italy, 2017–2019, by sequence type

*Sequence types (STs) represented by <3 isolates.
be imported by living animals or traveling humans, or they may have been derived from an early mixing of pig breeds, as previously hypothesized (3,40).

All serotype 7 isolates belonged to ST29, grouped in cluster 4, and had 2 mrp gene variants. The same characteristics were described for serotype 7 ST29 isolates from recent severe outbreaks among piglets in Germany and Austria (18). Thus, ST29 has been suggested as an emerging virulent sequence type in Europe (18).

In contrast to the serotype 2 and 1/2 isolates, serotype 9 isolates were distributed among different clusters in the phylogenetic tree, grouping with isolates belonging to other serotypes. High heterogeneity has been reported for serotype 9 (11,44). Three isolates from our collection were typed as serotype 9 ST16, a dominant clone in diseased pigs from the Netherlands (3). Although most cases in humans have been attributed to ST1 isolates, ST16 has recently been associated with cases of S. suis infection in humans in Thailand (13). It has been suggested that the zoonotic and virulence potential may be higher for ST16 than for other strains. In our study, the ST16 subgroup was related to CCI, harbored mrp and sly genes, and was close to ST1 and ST7 in the phylogenetic tree, in accordance with the results reported by Zheng et al. (10). The presence of ST16 in Italy suggests the need for monitoring and typing S. suis from diseased pigs and infected humans in a One Health scenario.

A large proportion of serotype 9 isolates were assigned to ST123 and grouped into cluster 4 in the phylogenetic tree. This sequence type was prevalent in our collection and was found in 5 regions of Italy and
in pigs from different production companies. Most ST123 isolates were resistant to penicillin. ST123 was reported in Spain in 2009 (9). As already observed in Spain, the ST123 isolates from our study were related to the ST94 subgroup and were characterized by the presence of sly and mrrPASA genes (10).

The number of live pigs imported into Italy has increased over the past 10 years, almost doubling from 2013 to 2018 (http://www.anas.it). Pigs are imported from other countries in Europe, predominantly the Netherlands, Denmark, and Germany, and, to a lesser extent, from Spain and countries in eastern Europe. Imported live pigs can be carriers of new *S. suis* clones, which may then be transferred to other animals at the receiving farm (11). The differences in the *S. suis* population in our study compared with those in previous studies may result from this intensive exchange of live pigs between Italy and other countries in Europe.

We confirmed widespread resistance to tetracycline and clindamycin, as previously reported for *S. suis* isolates globally. Resistance to tetracycline was mainly associated with the presence of tetO and, to a lesser extent, other tet genes, including tetM and the mosaic gene tet (O/W/32/O), which was first described in *S. suis* isolates in Italy (1). Resistance to clindamycin was coupled with high MICs for tylosin and the diffuse presence of ermB, suggesting a macrolide/lincomamide/streptogramin B profile. Resistance to florfenicol was detected in 2 multiresistant isolates. This type of resistance is emerging in *S. suis* species (45). One of the florfenicol-resistant isolates was positive for optrA, an oxazolidinone/phenicol resistance determinant carried by mobile genetic elements. optrA in *S. suis* isolates from China has been previously described and is frequently detected in *Enterococcus* isolates from pig farms in Italy (46,47). The high levels of AMR and the detection of emerging drug-resistance determinants are a consequence of selective pressure caused by antibiotic overuse. Despite the declining trend in antibiotic consumption, the use of antibiotics in veterinary medicine is still more frequent in Italy than in other countries in Europe (48).

We observed a high level of resistance to penicillin; ≥1 in 5 isolates showed reduced susceptibility to this antimicrobial. This finding contrasts with previous observations from other countries in Europe (15,49). Resistance to ampicillin was not observed, thus confirming the hypothesis of incomplete cross-resistance between these 2 antimicrobials (49). Resistance to penicillin was mostly detected in serotype 9 isolates and was particularly frequent in ST123 isolates. Blume et al. (9) suggested that the spread of *S. suis* serotype 9 is favored by the selective advantage conferred by the absence of heterologous immunity induced by the dominant serotype 2 clone (9). Our data suggest that penicillin resistance may also be a driver of the expansion of *S. suis* serotype 9.

The emergence of a penicillin-resistant clone among the *S. suis* population threatens the successful treatment of *S. suis* infections in pigs. Penicillin resistance in *S. suis* may favor the prescription of critical classes of antimicrobial drugs, which should be limited in veterinary medicine. Penicillin resistance in a zoonotic agent raises concerns about hampering the treatment of infections.

In conclusion, our study highlights the value of characterizing *S. suis* isolates from pigs for monitoring trends in AMR and enabling early detection of emerging clones. In addition, our data strongly suggest the need for preventive strategies to limit the spread of penicillin-resistant *S. suis* among pig populations in Italy.

Appendix 2

**Read quality, number of contigs and coverage of Whole-Genome Sequencing data**

The final assembly of the 78 sequences resulted in an average read quality after trimming of 34.60% (min 34.04, max 34.89) and 3,165,852 read pairs (min 1,043,985; max 5,077,416). The average number of contigs was 68 (min 25, max 177), with a mean length of 2,114,359 nucleotides (min 2,026,262; max 2,264,709). The average vertical coverage was 211 (min, 69; max, 339). The mean N50 and L50 values were 149,502 nucleotides (min 371, 66; max 293,044) and 6.95 (min 3, max 21), respectively.

Page 7 of 10
Appendix 2 Figure 1. e-BURST illustration of the Streptococcus suis population was used together with the complete MLST database to cluster the sequence types (STs) into major clonal complexes (CCs). The representation of groups was performed with the double-locus variants (DLVs) parameters. Primary founders (green) are positioned at the center of the cluster and subgroup founders are showed in yellow. The new STs described in our study are highlighted in red.
Appendix 2 Figure 2. Results of comparison between the genomes of our ST7 with the genomes of CS100322 and SC070731, two novel ST7 types described by Dong et al. (7) as belonging to lineage III, with SC84 and SC19, two ST7 lineage I strains, and with P1-7 as reference strain. The figure was generated using Phandango, an interactive viewer for bacterial population genomics (https://jameshadfield.github.io/phandango/#/) using as input the file generated by Roary (gene_presence_absence.csv and accessory_binary_genes.fa.newick). Genes are shown as light blue bricks along the top and are sorted left to right by the proportion of isolates they are observed in. Presence (blue) and absence (white) of genes are plotted considering the phylogenetic placement of each isolates.
