The Great American Biotic Interchange revisited: a new perspective from the stable isotope record of Argentine Pampas fossil mammals

Laura Domingo¹,²*, Rodrigo L. Tomassini³, Claudia I. Montalvo⁴, Dánae Sanz-Pérez¹ & María Teresa Alberdi⁵

This study aims at assessing resource and habitat use, niche occupation and trophic interactions from a stable isotope perspective on fossil mammals from the Argentine Pampas during the Great American Biotic Interchange (GABI). We present stable isotope data of more than 400 samples belonging to 10 mammalian orders and spanning a temporal range from ~9.5 Ma to ~12 ky. Rodents, notoungulates and pilosians record an increase in the consumption of C₄ plants, whereas litopterns and cingulates show δ¹³C values that remain mostly within a C₃-dominated diet. Our stable isotope data indicates that the expansion of C₄ vegetation opened up new niche opportunities, probably alleviating resource competition among endemic taxa. Gomphothere, equid and camelid δ¹³C records show a broad variability pointing to consumption of C₃ and mixed C₃-C₄ vegetation. This flexible dietary behavior may have facilitated the successful settlement of immigrant groups in South America. In the case of carnivorous taxa, Late Miocene pre-GABI endemic sparassodonts consumed prey from C₃ environments, whereas immigrant carnivorans preferred prey from mixed C₃-C₄ areas. Our research contributes to the study of the GABI from a different perspective as stable isotope records permit to characterize, from a (semi)quantitative standpoint, ecological traits within extinct fauna.

Understanding the evolution of mammalian communities throughout the history of Earth, their resource and habitat use, niche occupation and trophic relationships play fundamental roles as these variables determine interaction among species, which ultimately trigger profound changes in community structure leading to modern faunal structure².

The Late Cenozoic fossil record of South America provides a unique natural laboratory to investigate faunal response in the context of changing biotic and abiotic forces². Recent works on the tectonism, paleoceanography, paleobiogeography and paleobiology of the Isthmus of Panama have refined our knowledge of its final formation, although not without controversy and sometimes opposing views about its tempo and mode². Despite debates about tectonic vs. ecological barriers to intercontinental faunal exchange, most workers accept that South America was mostly isolated from other continents for more than 50 Ma, from the Late Paleocene until regular terrestrial faunal exchange began following the establishment of the Panama corridor⁴,⁵.

The Great American Biotic Interchange (GABI) occurred in pulses, reflecting intermittent connections due to sea level lowstands and glacial-interglacial climatic dynamics⁴,⁵. The first arrival of North American taxa into South America took place in the Late Miocene (Huayquerian) before the total establishment of the Panama corridor. Herald taxa were procyonids, cricetids and later on, tayassuids. Then, once the land bridge was completed.
by 3.1–2.7 Ma, the full GABI took place, with the entrance of other immigrant groups8. The magnitude of initial biotic interchange during GABI was roughly proportional to the diversity of each “donor” continent, but North American mammals radiated more successfully in South America 7,9. While there is a good chronology of the GABI pulses, little is known about the resource and habitat use, niche occupation and trophic interactions in South America related to this event or the extent to which the arrival of northern mammals affected ecological attributes. In this sense, previous stable isotope studies on vertebrate taxa have greatly contributed to unveil these questions10–17.

Through the investigation of stable isotope data on a complete and updated record of Late Miocene to Late Pleistocene fossil mammals from Argentina (La Pampa and Buenos Aires provinces) selected in this study, CB: Cerro La Bota, AC: Arroyo Chasicó, Te: Telén, Qu: Quehué, SG: Salinas Grandes de Hidalgo, BG: Bajo Giuliani, Ca: Caleufú, FM: Farola Monte Hermoso, TR: Toscas del Río de La Plata, Lu: Luján, BA: Buenos Aires city area, RS: Río Salado, AT: Arroyo Tapalqué, PO: Paso Otero, CP: Cascada del Paleolama, PB: Playa del Barco, SR: Santa Rosa, ZS: Zanjón Seco. Samples from Arroyo Chasicó locality include fossils from Late Miocene (Chasicoan = C) and the Late Pleistocene (Lujanian = L) levels. Satellite images were freely downloaded from the Instituto Geográfico Nacional de Argentina. QGIS Desktop 3.2.3 with GRASAS 7.4.1 free software was used to assemble images (https://www.qgis.org/es/site/).

![Figure 1. Geographical setting of the studied paleontological localities. (A) General map of South America. (B) Detailed map showing the situation of the Late Cenozoic fossil sites from Argentina (La Pampa and Buenos Aires provinces) selected in this study.](https://www.nature.com/scientificreports/)

Selected fossiliferous localities situated in the Pampean region (La Pampa and Buenos Aires provinces), include faunal associations that represent different stages/ages18,19 (and references therein) spanning a temporal interval from pre-GABI times (~9.5 million years (Late Miocene, Chasicoan) to ~12,000 years (Late Pleistocene, Lujanian) (Fig. 1). In the present study, we analysed carbon and oxygen stable isotope compositions on fossil tooth enamel belonging to 8 mammalian orders and orthodentine belonging to xenarthran remains (Pilosa and Cingulata) from Pampean localities (Fig. 1, Supplementary Tables S1 and S2). Stable isotope analysis constitutes a proxy widely used to characterize paleoecological, paleoclimatic and paleoenvironmental variability (e.g. 13,20; see Supplementary Text). Bioapatite δ¹³C values allows the characterization of the diet of extinct taxa, as well as the reconstruction of past habitat preferences, whereas bioapatite δ¹⁸O values record the δ¹⁸O value of body water reflecting changes in the isotopic composition of ingested water, which mainly varies with mean annual temperature and aridity20. By focusing on a specific region, we can overcome stable isotope biases due to particular hydrological, geographical, and/or vegetational conditions that may have existed among different geographical areas. Repeated stable isotope analyses on selected samples strongly support the reproducibility of the data (see Supplementary Text). Analytical methods follow well-established protocols for carbon and oxygen stable isotope analyses (see the Materials and methods section and Supplementary Text).
Results and Discussion

δ13C change through the GABI temporal interval. Bioapatite δ13C values for Rodentia, Notoungulata, Litopterna, Pilosa, Cingulata, Proboscidea, Perissodactyla, Artiodactyla, Sparassodonta and Carnivora are shown in Fig. 2 and Supplementary Tables S1 and S2. As for the dietary-bioapatite δ13C enrichment (ε∗diet-enamel), we use ε∗diet-enamel of +14.1‰21 for all orders (except for rodents and xenarthrans), +12.8‰ for rodents22, and ε∗diet-enamel of +15.6‰ for xenarthrans23. Sparassodonts and carnivorans show raw δ13C data (solid symbols) and δ13C data corrected for the trophic offset (open symbols), adding 1.3‰ to the raw values24. Locality abbreviations are the same as in Fig. 1. *Late Pleistocene (Lujanian) perissodactyl samples come from Luján, Río Salado, Arroyo Tapalqué, Cascada del Paleolama, Zanjón Seco, Paso Otero and Arroyo Chasicó localities (Supplementary Table S1). **Late Pleistocene (Lujanian) artiodactyl samples come from Playa del Barco, Santa Rosa, Cascada del Paleolama and Paso Otero localities (Supplementary Table S1). Zig-zag lines in the chronology tables denote non-represented ages: the Montehermosan is followed by the Chapadmalalain, the Marplatian, the Ensenadan, the Bonaerian, and the Lujanian.

Figure 2. Bioapatite δ13C (%‰, VPDB) values of 10 orders of herbivore and carnivore mammals from the La Pampa and Buenos Aires provinces between the Late Miocene (Chasicoan) and the Late Pleistocene (Lujanian). (A) Rodentia, (B) Notoungulata, (C) Litopterna, (D) Pilosa, (E) Cingulata, (F) Proboscidea, (G) Perissodactyla, (H) Artiodactyla, (I) Sparassodonta, (J) Carnivora. The grey bars represent the vegetation δ13C cut-off values between a C3-dominated diet, an intermediate C3-C4 diet, and a C4-dominated diet. The lightest grey denotes an δ∗diet-enamel of +14.1‰21, whereas the darkest one corresponds to a δ∗diet-enamel of +12.8‰ for rodents22, and δ∗diet-enamel of +15.6‰ for xenarthrans23. Sparassodonts and carnivorans show raw δ13C data (solid symbols) and δ13C data corrected for the trophic offset (open symbols), adding 1.3‰ to the raw values24. Locality abbreviations are the same as in Fig. 1. *Late Pleistocene (Lujanian) perissodactyl samples come from Luján, Río Salado, Arroyo Tapalqué, Cascada del Paleolama, Zanjón Seco, Paso Otero and Arroyo Chasicó localities (Supplementary Table S1). **Late Pleistocene (Lujanian) artiodactyl samples come from Playa del Barco, Santa Rosa, Cascada del Paleolama and Paso Otero localities (Supplementary Table S1). Zig-zag lines in the chronology tables denote non-represented ages: the Montehermosan is followed by the Chapadmalalain, the Marplatian, the Ensenadan, the Bonaerian, and the Lujanian.

δ13C change through the GABI temporal interval. Bioapatite δ13C values for Rodentia, Notoungulata, Litopterna, Pilosa, Cingulata, Proboscidea, Perissodactyla, Artiodactyla, Sparassodonta and Carnivora are shown in Fig. 2 and Supplementary Tables S1 and S2. As for the dietary-bioapatite δ13C enrichment (ε∗diet-enamel), we use ε∗diet-enamel of +14.1‰21 for all orders (except for rodents and xenarthrans), +12.8‰ for rodents22, and +15.6‰ for xenarthrans23. Carnivorans’ trophic fractionation was also accounted for24 (see Supplementary Text).

The most noticeable feature is an overall increase of δ13C values for some of the endemic herbivore mammals (rodents, notoungulates, pilosians) recorded between the Late Miocene and the Pleistocene (Fig. 2). The increase in the bioapatite δ13C values of these taxa is intrinsically related to a shift in the use of plant resources from C3-dominated vegetation to mixed C3-C4 vegetation. The expansion of C4-dominated grasslands in Argentina has been recorded at ~8–7 Ma11. The rising of C4 plants at the Pampean region is framed within the timing of the “Edad de las Planicies Australes” (“Age of Southern Plains”), a period between 11 and 3 Ma characterized by an increase in aridity, a gradual decrease in temperatures and the establishment of vast grasslands after the retreat of the Paranean Sea18. The shift in our stable isotope data support the premise posed by MacFadden et al.10, who stated that after ~8 Ma, the Pampean ecosystem was characterized by a mix of C3 trees, shrubs and grasses, as well as C4 grasses. Unfortunately, there is not a good paleobotanical/palynological record in the Pampean deposits5, which makes the study of stable isotopes on vertebrate bioapatite of utmost interest in the understanding of vegetation evolution in the Pampean area during the late Cenozoic.
Representatives of the orders Rodentia and Notoungulata show relatively high bioapatite δ¹³C values at the Chasicoan (~9.5 Ma, Late Miocene), including Arroyo Chasico and Cerro La Bota localities, that remain close to the δ¹³C cut-off value between a C₃-dominated diet and a C₃-C₄ diet (Fig. 2A,B). As the proportion of C₄ plants within Pampean ecosystems may not have been significant until the latest Miocene, these high bioapatite δ¹³C values may be pointing to the consumption of C₃ plants from xeric environments. However, we cannot fully discard the fact that C₃ plants may have already found favorable conditions to thrive at this early age in the Pampean area as also suggested by Hynek et al. ¹² for the Northwest of Argentina. Rodentia, Notoungulata and Pilosa fed on a C₃-C₄ environment later in the Late Miocene/Early Pliocene Caleufú ¹⁶ and Early Pliocene Farola Monte Hermos ⁹ localities (Fig. 2A,B,D). This trend towards an increase in the use of C₄ resources is not as marked in Litopterna and Cingulata, which show δ¹³C values that remain mostly within a C₃-dominated diet throughout the studied temporal interval (Fig. 2C,E). During the Pleistocene, notoungulates and pilosians show intermediate C₃-C₄ diets (Fig. 2B,D), whereas endemic litopterns and cingulates along with immigrant proboscideans, perissodactyls and artiodactyls show diets at the interplay between a C₃-dominated diet and a mixed C₃-C₄ diet (Fig. 2E–H).

Rodentia. The dietary change recorded in rodent δ¹³C values is detected at the Late Miocene/Early Pliocene Caleufú and Early Pliocene Farola Monte Hermos localities (Fig. 2A). This shift is statistically significant when compared to older localities from the Late Miocene (Arroyo Chasico and Salinas Grandes de Hidalgo) (Supplementary Table S3). In our study, evaluated remains from Caleufú include Caviidae and Dinomyidae, whereas Farola Monte Hermos is represented by Caviidae and Chinchillidae. All of them have a wide range of δ¹³C values that was not observed among these same families in older localities (Fig. 2A, Supplementary Table S2). Therefore, studied rodents were able to incorporate C₄ resources to their previous C₃-dominated diet as soon as C₄ vegetation was available in the region. This is in agreement with Hynek et al. ¹², who observed a wide δ¹³C range on rodent tooth enamel in the Pliocene deposits from Northwestern Argentina, evidencing the consumption of C₄ vegetation at this time.

Notoungulata. Chasicoan notoungulates from the Arroyo Chasico (Late Miocene) locality are represented here by different taxa of the families Toxodontidae, Hegetotheriidae, Mesotheriidae and Homalodotheriidae (Supplementary Table S2). Only the first three are represented in Late Miocene Cerro La Bota (Chasicoan), Telén, Quehué and Salinas Grandes de Hidalgo (Huayquerian). Chasicoan notoungulates show a wide δ¹³C range indicative of dietary flexibility from more forested-arboreal areas to open grasslands within a C₃-continuum (Fig. 2B, Supplementary Table S2). Some of the Arroyo Chasico and Cerro La Bota notoungulate δ¹³C values surpass the vegetation δ¹³C threshold value between a C₃-dominated diet and a C₃-C₄ diet. It is likely that they may be recording a C₃ diet within open xeric conditions as C₄ plants were not still present in significant proportions at this time ¹⁵, although this result may as well point to the existence of favorable climatic and environmental conditions for C₄ photosynthesis at this early time as suggested by Hynek et al. ¹², Huayquerian notoungulate δ¹³C record starts with a decrease indicating a pure-C₃ diet at this time period (Fig. 2B, Supplementary Table S2). Therefore, the shift in tooth enamel δ¹³C values represents a real change in resource use (not family-biased) for the faunas assigned to the Huayquerian. As observed in rodents, notoungulates record a significant shift in their δ¹³C values from the most modern Neogene faunas onwards (Fig. 2B, Supplementary Tables S2 and S3). In this context, the notoungulates from the Late Miocene/Early Pliocene Caleufú and Early Pliocene Farola Monte Hermos localities, represented in our study by Toxodontidae, Hegetotheriidae and Mesotheriidae, depict a wide range of tooth enamel δ¹³C values around the boundary between C₃-dominated and C₃-C₄ diets (Fig. 2B, Supplementary Table S2). Our results suggest that notoungulates changed their dietary preferences at the end of Miocene-beginning of the Pliocene, taking advantage of the expansion of C₄ vegetation in the region, with hegetotherids and mesotherids likely developing a more flexible resource use and toxodontids adopting a more specialised intermediate C₃-C₄ diet. Toxodontids (Toxodon) from the Quaternary Late Pleistocene Playa del Barco and Santa Rosa sites retained this newly adopted dietary behavior becoming important dwellers of intermediate C₃-C₄ areas (Fig. 2B, Supplementary Tables S2 and S3). Our results agree well with previous stable isotope analyses on notoungulates from other fossil sites in South America ¹²,2⁰,2⁸. These studies argued that the notoungulate dietary shift is pinpointed between 7 and 5.6 Ma and that this shift was independent from the notoungulate family, as also suggested by our results.

Litopterna. Litopterns from the Late Miocene Arroyo Chasico (Chasicoan) and Salinas Grandes de Hidalgo (Huayquerian) localities show a C₃-dominated diet, with a wide range of δ¹³C values indicative of a continuum from forested areas to more open conditions (Fig. 2C, Supplementary Table S2). These results agree well with the δ¹³C values from Salinas Grandes de Hidalgo provided by MacFadden et al. ¹². Litopterns from the Early Pliocene Farola Monte Hermos locality, represented by Macraucheniiidae and Prototheriidae, show a narrower range of tooth enamel δ¹³C values, but still within a C₃-dominated diet (Fig. 2C, Supplementary Table S2). Overall, our litoptern δ¹³C record does not track the expansion of C₄ plants in the region, contrary to rodents and notoungulates. With respect to the Quaternary taxa, Macraucheniiidae from the Early Pleistocene Toscas del Rio de La Plata locality (Ensenadan) still had a C₃-dominated diet, although with some values close to the C₃-C₄ transition, whereas Late Pleistocene (Lujanian) Macrauchenia from Arroyo Chasico, Paso Otero and Cascada de Paleolama shows a slight shift towards more mixed C₃-C₄ diet, although the low number of samples from this time period precludes us from making a more solid statement (Fig. 2C, Supplementary Table S2). Our results are supported by previous studies from the Quaternary localities of Camet Norte (Argentina) ¹⁵ and Tarija (Bolivia) ²⁹.

Pilosa and Cingulata. A diageneric test was performed to check whether the analysed xenarthran orthodentine retained the original isotopic signal (Supplementary Text, Supplementary Table S4). Bocherens et al. ³⁶ measured
the difference between collagen and bioapatite δ13C values within a same specimen and suggested that glyptodonts (Cingulata) and ground sloths (Pilosa) would have been herbivorous. Although in our record Xenarthra data points are scattered and scarce, it is notable the shift observed in the pilosian δ13C values from a C3-pure diet at the Late Miocene to a C4-based diet at the Pliocene and Pleistocene (Fig. 2D). Nothrotheriidae from the Late Miocene Arroyo Chasico (Chasicoan) and Mylodontidae from Salinas Grandes de Hidalgo (Huayquerian) localities depict a δ13C value indicative of a diet based on C4 items. Later on, Mylodontidae from the Late Miocene/Early Pliocene Caleufu and Early Pliocene Farola Monte Hermoso localities record higher δ13C values pointing to a shift towards the consumption of C4-C6 vegetation from more open spaces, tracking the expansion of C4 plants in the region (Fig. 2D, Supplementary Table S2). Finally, pilosians from the Late Pleistocene Playa del Barco and Santa Rosa localities, represented by Mylodontidae and Megatheriidae, show a marked dietary change, with an overall consumption of C4-C6 resources (Fig. 2D, Supplementary Table S2). Cingulata orthodentine δ13C record (Fig. 2E, Supplementary Table S2) does not show such a marked shift through time: pamphatheriids from the Late Miocene Arroyo Chasico (Chasicoan) and glyptodontids and dasypodids from Telén, Quehué and Salinas Grandes de Hidalgo (Huayquerian) localities depict δ13C values indicative of a diet based on C3 items, whereas glyptodontids from localities from the Late Pleistocene Buenos Aires city area show a wide range of δ13C values, with most of individuals consuming C3-dominated resources and others incorporating mixed C3-C4 resources (Fig. 2E, Supplementary Table S2). Our Quaternary xenarthran results are in line with those reported by Bocherens et al.18, whose collagen δ13C analyses on Late Pleistocene cingulates and pilosians from the Buenos Aires province point to a greater consumption of C4 resources in the latter.

**Proboscidea.** Gomphotheriidae (Stegomastodon) from the Early Pleistocene Toscas del Rio de La Plata and Late Pleistocene Playa del Barco and Buenos Aires city area localities show wide ranges of δ13C values pointing to a flexible diet, which would have included pure-C3 and mixed C3-C4 plant resources (Fig. 2F, Supplementary Table S2).

**Perissodactyla.** Equids from the Early Pleistocene Toscas del Rio de La Plata locality have δ13C values indicative of a C3-dominated diet. On the other hand, *Equus* and *Hippidion* from different Late Pleistocene (Lujanian) sites show a broad variability of δ13C values pointing to consumption of C3 and mixed C3-C4 vegetation (Fig. 2G, Supplementary Table S2), similarly to what is observed in the case of gomphotherii.

**Artiodactyla.** Artiodactyls from the Early Pleistocene Toscas del Rio de La Plata locality are represented by Camelidae. *Lama* sp. records significantly lower δ13C values indicative of a browsing diet in a more wooded area, when compared to other camels, assigned to *Palaeolama* sp., with higher δ13C values pointing to a more intermediate diet (t = −1.361, p = 0.042) (Fig. 2H, Supplementary Table S2). At the Late Pleistocene Playa del Barco site, artiodactyls are represented by the cervid *Morenelaphus*, which shows the lowest δ13C values among our artiodactyl record (Supplementary Table S2), pointing to a browsing C3-diet and occupation of wooded areas. At the Late Pleistocene Santa Rosa locality, the camels *Lama* and *Hemiauchenia* seem to have partitioned resources to some extent, with the former showing significantly lower δ13C values and the latter recording higher δ13C values (t = −3.492, p = 0.025) (Supplementary Table S2).

Dietary flexibility evidenced by northern immigrants (proboscideas, perissodactyls and artiodactyls) as shown by our δ13C values and other isotopic studies from North and South America13,15,30–33, and by extension, their plasticity in niche occupation, is in agreement with the habitat theory proposed by Vrba14 according to which generalists and open biome specialists from North America experienced a successful radiation throughout South America14,35.

**Sparassodonta.** Endemic sparassodonts are represented by the carnivorous and scansorial borhyaenoid *Lycopsis* from the Late Miocene Quehué and Salinas Grandes de Hidalgo localities. Sparassodont δ13C record reveals a consumption of prey from open areas (Fig. 2I, Supplementary Table S2). We used MixSIAR mixing model to estimate the proportions of source (prey) contributions to a consumer (predator)16 (see the Materials and methods section and the Supplementary Text). Late Miocene sparassodonts preferentially preyed on notoungulates (Supplementary Table S5).

**Carnivora.** Immigrant Carnivora from the Late Pleistocene Playa del Barco and Santa Rosa sites are represented by the hyper-carnivorous felid *Smilodon*, whose δ13C values point to the ingestion of prey species from mixed C3-C4 areas (Fig. 2J, Supplementary Table S2). MixSIAR results indicate that the analysed specimens from Playa del Barco preferentially preyed on notoungulates, whereas analysed specimens from Santa Rosa preferentially preyed on perissodactyls (Supplementary Table S5). In our study, *Smilodon* potential prey from mixed C3-C4 areas point to an intermediate situation between the ones provided by Cotte et al.17 and Bocherens et al.18. Cotte et al.17 carried out δ13C analyses on Late Pleistocene *Smilodon* tooth enamel from the Buenos Aires province and suggested that it mainly preyed on species from wet areas with C3 vegetation. Bocherens et al.18 performed δ13C analyses on Late Pleistocene *Smilodon* collagen from the same province, but their results point to *Smilodon’s* consumption of prey from open landscapes. This disparity may be indicative of its ability to hunt on a wide range of habitats and species.

Differences between Sparassodonta and Carnivora δ13C values are statistically significant (t = −17.746, p < 0.001) evidencing a different resource use and indirectly mirroring the expansion of C4 vegetation.

**Niche occupation through the GABI.** Isotopic niches were assessed by using a Bayesian approach described in the Materials and methods section and the Supplementary Text. In the Pre-GABI Late Miocene Arroyo Chasico locality, rodents, notoungulates and litopterns show some degree of ellipse (niche) overlap...
Overall, taxa ingested vegetation from C₃ areas, although notoungulates seem to have significantly incorporated C₃ plants from more open spaces, whereas rodents and litopterns consumed C₃ vegetation from more wooded areas (Supplementary Table S6). δ¹⁸O are driven by particular water use, ecologies and ecosystem preferences among different taxa and therefore, we consider this isotopic system in the assessment of habitat use, which along with the evaluation of resource use can help us depict niche occupation and width. In this sense, fitted loess δ¹⁸O curves along time depicted in Fig. S1 show different patterns for each order probably reflecting particular water use, rather than recording global climatic trends. At Arroyo Chasicó, rodents show significantly lower δ¹⁸O values (Fig. 3A, Supplementary Table S6) when compared to notoungulates and litopterns, which may point to ingestion of water (either via drinking or food) subject to a lower degree of evaporation. Rodents have narrower home ranges when compared to large mammals, so they could be tracking more local conditions, whereas notoungulates and litopterns would provide a more integrated signal of their broader home ranges. In this sense, notoungulates and litopterns do not show significantly different δ¹⁸O values (Fig. 3A, Supplementary Table S6), which point to ingestion of water subject to similar hydrological conditions. The δ¹³C-δ¹⁸O ellipses could not be retrieved for xenarthrans and sparassodonts since they have fewer than three datapoints, although most of them fall within a C₃-dominated area (sparassodonts would have used prey from these areas). They show overall low δ¹⁸O values indicative of water ingestion with a lower degree of evaporation (Fig. 3A).

At the Late Miocene Salinas Grandes de Hidalgo locality, which evidences the first pulse of the GABI through the presence of the procyonid Cyonasua (not sampled in this study), there is a more intense ellipse (niche) overlap among the analyzed taxa (Fig. 3B). As observed in the case of the Arroyo Chasicó locality, all taxa consumed C₃ vegetation (or preyed on taxa with a pure C₃ diet in the case of sparassodonts), but their δ¹³C values are more condensed (Supplementary Table S6) and reflect their coexistence in a C₃ woodland to open C₃ grassland (Fig. 3B). Also δ¹⁸O values show a more intense overlap (Supplementary Table S6), pointing to ingestion of water subject to similar hydrological conditions. The more intense ellipse (niche) overlap and the contraction of ellipse (niche) breadth observed at this locality when compared to the Arroyo Chasicó locality may be indicative of tougher conditions related to increasing aridity reported previously for the end of the Miocene.

During the latest Miocene and Early Pliocene, the expansion of C₄ plants at the Pampean area occurred. If at this time some of the endemic herbivore taxa were able to incorporate C₄ vegetation, this may have eased the competition among fauna and favored their sympathy. This is illustrated by the significant change in the δ¹³C
values of rodents, notoungulates and pilosians at the Late Miocene/Early Pliocene Calefú and Early Pliocene Farola Monte Hermoso localities (Fig. 2A,B,D). Farola Monte Hermoso rodents, notoungulates and pilosians retrieved ellipses that evidence a more intense use of open C3 and/or C4 vegetation when compared with previous times (Fig. 3C). Rodents show the widest range of δ13C values (Fig. 3C) pointing to the consumption of a broad array of resources that include both C3-dominated and mixed C3-C4 vegetation. Rodents also show significantly different δ18O values when compared to notoungulates and litopterns (Supplementary Table S6), pointing to ingestion of water subject to different hydrological conditions (less intense evaporation) probably related to more local conditions and the ecology of some groups (e.g., fossil capybaras -Phugatherium, Hydrochoeriinae, Caviidae, - are recorded associated to water bodies). Notoungulates and pilosians show high δ13C values indicative of the use of C3 and C4 plants from more open spaces when compared to litopterns (Fig. 3C; Supplementary Table S6). It is noticeable the fact that this relationship between notoungulates and litopterns is maintained since the Chasicoan, something that has been supported by other lines of evidence, such as dental and body morphology 49. Overlapping δ18O values among notoungulates, litopterns and pilosians point to water use from sources subject to similar hydrological regime (Fig. 3C; Supplementary Table S6). Another interesting observation that is consistent at the Chasicoan, Huayquerian and Montehermosan (Fig. 3A–C) lies in the fact that rodent δ13C and δ18O values show a positive covariation. Lower resource δ13C values correspond to lower (drinking or food) ingested water δ18O and vice versa pointing to more closed or more open areas, respectively. This relationship is not observed in the case of larger taxa supporting the idea that rodents may be better recorders of ecosystem variability at a more local level.

North American herald taxa such as cricetids 26 and procyonids 40 are recorded in the Pampean region since the Late Miocene/Early Pliocene (Huayquerian). Then, the massive entrance of northern fauna took place once the Panaman Isthmus was fully established. Therefore, the shift in vegetation use by endemic fauna evidenced by our isotopic data at the Calefú (late Huayquerian) and Farola Monte Hermoso (Montehermosan) sites was not a consequence of pressure caused by new arrivals.

Global records point to optimal climatic conditions at this interval, when reorganized ocean circulation, perhaps associated with initial restriction of circulation between the Pacific and Atlantic, contributed to the Pliocene Warm Period between ~4.7 and 3.1 Ma 44. Based on the faunal assemblage, warm conditions, with open xerophytic woodlands and grasslands, similar to today’s Chacoan phytogeographic province, but probably with greater humidity, were proposed for Farola Monte Hermoso locality. A global cooling coincident with expansion of ice in Antarctica happened at ~3.0 and 2.7 Ma, marking the beginning of the Quaternary 42. The main GABI events are contemporary to this climatic deterioration, which accompanied by more arid conditions favored the development of open areas in South America and the establishment of a savanna corridor between North and South America facilitating the colonization by generalists and open biome specialists from North America 42,43. South American endemic fauna experienced a large number of extinctions at the Late Pliocene (Sanandresian) and Early Pleistocene (Ensenadan) 18. Although initial studies pointed to the arrival of northern immigrants as the trigger of this extinction events 45, more recent research suggests that the entrance into the Pampean region was gradual and that the biomass represented by these new taxa was insignificant at this moment and therefore, the global cooling is proposed as the main triggering factor of the extinction 41,46. The interaction with northern immigrants became more important since the Early Pleistocene (Ensenadan) and Middle Pleistocene (Bonaerian) and it was particularly keen during the Late Pleistocene (Lujanian). We lack isotopic data from the Bonaerian fauna, but our record of the Ensenadan and Lujanian endemic taxa, such as notoungulates and pilosians, shows a modification in their vegetation ingestion towards a more generalist intermediate C3-C4 diet (Figs. 2 and 3).

At the Late Pleistocene Playa del Barco locality, the faunal configuration is mainly characterized by the presence of large and megamammals. The analyzed taxa show a marked change in the resource use, with the full incorporation of mixed C3-C4 vegetation typical of grasslands at the Pampean area (Fig. 3D). Notoungulates, pilosians and perissodactyls almost exclusively consumed C3-C4 whereas proboscidians also incorporated plants from C3-dominated open areas (Fig. 3D, Supplementary Table S6). Felids (Smilodon) preyed on taxa that consumed mixed C3-C4 vegetation with mixing models pointing to notoungulates as their possible preferred prey (Fig. 3D, Supplementary Tables S5 and S6). Artiodactyla, exclusively represented by the cervid Morenelaphus, is the only order that shows a clear resource partitioning. Their significantly lower δ13C values evidences the consumption of C3 plants from more wooded spaces (Fig. 3D, Supplementary Table S6). Their higher δ18O values (Fig. 3D, Supplementary Table S6) may be related to either ingestion of drinking water or plant water subject to a higher degree of evaporation.

At the Late Pleistocene Santa Rosa locality, also large and megamammals are represented (Fig. 3E). Notoungulates and pilosians show similar dietary preferences (mixed C3-C4 vegetation) to that depicted at Playa del Barco. Artiodactyla are represented by camelds, whereas perissodactyls are represented by equids, both showing δ13C values indicative of a C3 diet from open areas and an intermediate C3-C4 diet (Fig. 3E). Similarly to that observed at Playa del Barco, felids (Smilodon) preyed on individuals that incorporated mixed C3-C4 vegetation, although the mixing model indicates that representatives of this locality probably preyed on perissodactyls (Fig. 3E, Supplementary Table S5). Santa Rosa taxa show overlapping and non-significantly different δ18O values (Fig. 3E, Supplementary Table S6), similar to those shown at Playa del Barco pointing to a similar hydrological regime.

Northern newcomers such as probocisdeans, perissodactyls and camels had a flexible dietary behavior (from pure C3 to mixed C3-C4 diet, Fig. 2), which may have facilitated their successful radiation in South America as supported by their abundant fossil record in the continent (see 13). The case of cervids is noticeable since they showed a more restricted diet based on plant resources from C3-dominated areas (Figs. 2 and 3D, Supplementary Table S2). Cervids may have successfully radiated into South America by taking advantage of resources from wooded areas within a savanna habitat. According to Cione et al. 18, although the mammalian taxonomic diversity at the Late Pleistocene was high, the number of individuals per species and the total biomass...
Conclusions

The Argentine Pampas (Buenos Aires and La Pampa provinces) have proven to be one of the best research areas to study the GABI from the perspective of the South American fossil record on account of its elevated number of Late Cenozoic fossil sites with diverse and abundant vertebrate faunal remains. For this study, we carried out biapatite stable isotope analyses ($\delta^{13}C$ and $\delta^{18}O$) on a significant number of Pampean fossil mammalian remains belonging to 10 orders and spanning a temporal range from ~9.5 million years (Late Miocene, Chasicoan) to ~12,000 years (Late Pleistocene, Lujanian). Rodents, notoungulates and pilosians track the expansion of $C_4$ plants in the Pampean area during the latest Miocene/earliest Pliocene (Huayquerian/Montehermosan), whereas litopterns and cingulates kept mostly a $C_3$-dominated diet. North American taxa including gomphotheres, equids and camelsids record a large variability in their biapatite $\delta^{13}C$ pointing to consumption of $C_3$ and mixed $C_3$-$C_4$ vegetation facilitating their successful settlement in the Pampean region. Cervids kept a $C_3$-dominated diet, but were still able to thrive in their expansion into the South. In the case of carnivorous taxa, Late Miocene pre-GABI endemic sparassodonts preferentially preyed on species from open $C_3$ environments, whereas immigrant carnivores preferred prey from intermediate $C_3$-$C_4$ areas. Some of the selected taxa have never been explored from a stable isotope standpoint. Therefore, this study provides invaluable paleoecological and paleoenvironmental information from an isotopic perspective on late Cenozoic endemic and immigrant taxa implied in the GABI.

Materials and Methods

For this study, we analysed the carbon and oxygen isotope composition on the carbonate fraction of 338 mammalian bioapatite (tooth enamel and orthodentine) samples spanning a temporal interval from the Late Miocene (Chasicoan) to the Late Pleistocene (Lujanian) of the Argentine Pampas (Buenos Aires and La Pampa provinces) (Fig. 1, Supplementary Tables S1 and S2). Additionally, 72 bioapatite samples belonging to different Pleistocene taxa from localities situated at the Buenos Aires province were included in the database from a previous study (see 13). A rotary drill with a diamond-tipped dental burr was used to recover enamel and orthodentine from an area of the tooth as large as possible to avoid seasonal bias in the time of mineralization. The carbon and oxygen isotope results are reported in the $\delta$-notation $\delta{X}_{\text{Sample}} = \{(R_{\text{Sample}} - R_{\text{Standard}})/R_{\text{Standard}}\} \times 1000$, where $X$ is the element, $R$ is the mass of the rare, heavy isotope, and $R = {^{13}C}/^{12}C$ or $^{18}O/^{16}O$. Vienna Pee Dee Belemnite (VPDB) is the standard for $\delta^{13}C$ values, whereas Vienna Standard Mean Ocean Water (VSMOW) is the standard for $\delta^{18}O$ values. Sample chemical treatment followed the one described in Domingo et al. for carbonate in bioapatite. Analyses were conducted at the Stable Isotope Laboratory of the University of California Santa Cruz using a Thermo Scientific MAT253 dual inletsotope ratio mass spectrometer coupled to a Thermo Scientific Kiel IV carbonate device (see Supplementary Text for more details).

For diagenesis control, we measured the oxygen isotope composition of both the carbonate and phosphate fractions of 322 bioapatite samples (see Supplementary Text and Supplementary Tables S2 and S4). Sample chemical treatment followed the one described in Domingo et al. for phosphate in bioapatite. $\delta^{18}O_{\text{PO4}}$ values were measured at the Stable Isotope Laboratory of the University of California Santa Cruz using a Thermo Finnigan Delta plus XP isotope ratio mass spectrometer coupled via continuous flow to a high temperature conversion elemental analyzer (TCEA) (see Supplementary Text for more details).

We used R software version 3.1.1 (http://www.r-project.org/) for statistical analysis (Supplementary Tables S3 and S6) and graphical representation of the isotopic results.

We used MixSIAR mixing model to estimate the proportions of source (prey) contributions to a consumer (predator) (Supplementary Table S5). Mixing models find the combinations of prey proportions that are mathematically feasible solutions that would explain consumer isotope values. With the aim of not compromising the discriminatory power of the mixing model due to a large number of sources, we kept the source number below 6. MixSIAR results (posterior probabilities of dietary proportions) are reported as the median and 95% Bayesian credible intervals of the likely contribution of each prey taxon to the tissue composition of the predators. MixSIAR uses a Markov Chain Monte Carlo (MCMC) model-fitting algorithm. We evaluated isotopic niches using SIBER (Stable Isotope Bayesian Ellipses in R). To assess isotopic niche by means of SIBER it is necessary to use at least two isotopic systems (in our case, $\delta^{13}C$ and $\delta^{18}O$), which permit to delimitate a 2D $\delta$-space. SIBER also needs to be fed with at least three data point per taxon to retrieve ellipses. SIBER uses a Markov Chain Monte Carlo (MCMC) model-fitting algorithm to construct a standard ellipse area (SEA) that best fits each set of $\delta^{13}C$ and $\delta^{18}O$ from different members within a (paleo)community (i.e., different taxa). We evaluated the isotopic niche in those localities with a good representation of taxa (three or more orders) and where each order has a good sampling record to retrieve ellipses (three or more samples per order).

Data availability

All data generated or analysed during this study are included in this published article and in the Supplementary Information files.
