Charmed mesons in hot and dense matter are studied within a self-consistent coupled-channel approach for the experimental conditions of density and temperature expected at the CBM experiment at FAIR/GSI. The $D$ meson spectral function broadens with increasing density with an extended tail towards lower energies due to $\Lambda_c(2593)N^{-1}$ and $\Sigma_c(2800)N^{-1}$ excitations. The in-medium $\bar{D}$ meson mass increases with density. We also discuss the consequences for the renormalized properties in nuclear matter of the charm scalar $D_{s0}(2317)$ and $D(2400)$, and the predicted hidden charm $X(3700)$ resonances at FAIR energies.

1. Introduction

The CBM experiment of the future FAIR project will investigate highly compressed dense matter in nuclear collisions with a beam energy range between 10 and 40 GeV/u [1]. One of the goals is to extend the SIS/GSI program for the in-medium modification of hadrons and to provide first insight into charm-nucleus interaction. The study of the properties of elementary particles in nuclei helps to learn about not only the excitation mechanisms in the nucleus but also the properties of these particles. Thus, the possible modifications of the properties of open and hidden charmed mesons in a hot and dense environment are matter of recent analysis.

The in-medium modification of the open charm mesons ($D$ and $\bar{D}$) may explain the $J/\Psi$ suppression [2] in an hadronic environment, based on the mass reduction of $D(\bar{D})$ in the nuclear medium. However, a coupled-channel meson-baryon scattering in nuclear medium is needed due to the strong

2. Charm mesons in a hot nuclear environment

We study the spectral properties of $D$ and $\bar{D}$ mesons in nuclear matter at finite temperature by extending the result of Ref. [6]. The $D$ and $\bar{D}$ self-energies at finite temperature are obtained from a self-consistent coupled-channel calculation taking, as bare interaction, a type of broken SU(4) $s$-wave Tomozawa-Weinberg (TW) interaction supplemented by an attractive isoscalar-scalar term ($\Sigma_{DN}$). The transition matrix $T$ is solved using a cutoff regularization, which is fixed by reproducing the position and the width of the $I = 0 \tilde{\Lambda}_c (= \Lambda_c(2593))$ resonance while a new resonance in $I = 1$ channel $\tilde{\Sigma}_c (= \Sigma_c(2800))$ is then generated [6].

The in-medium solution at finite temperature incorporates Pauli blocking effects, baryon mean-field bindings via a temperature-dependent $\sigma - \omega$ model, and $\pi$ and open-charm meson self-energies in the intermediate prop-

Fig. 1. $\tilde{\Lambda}_c$ and $\tilde{\Sigma}_c$ resonances, and the $D$ meson spectral function

coupling among the $DN$ and other meson-baryon channels [3, 4, 5, 6, 7]. Moreover, changes in the properties of open charm will affect the renormalization of charm and hidden charm scalar mesons in nuclear matter, providing some information about their nature, whether they are $q\bar{q}$ states, molecules, mixtures of $q\bar{q}$ with meson-meson components, or dynamically generated resonances resulting from the interaction of two pseudoscalars.

In the present article, we pursue a coupled-channel study on the spectral properties of $D$ and $\bar{D}$ mesons in nuclear matter at finite temperature. We then analyze the effect of the self-energy of $D$ mesons on dynamically-generated charm and hidden charm scalar resonances, such as $D_{s0}(2317)$ and $D(2400)$, and the predicted hidden charm $X(3700)$.
agators (see [7]). The self-energy and, hence, spectral function are obtained self-consistently summing $T_{DN}$ over the nucleon Fermi distribution.

The $I = 0 \tilde{\Lambda}_c$ and $I = 1 \tilde{\Sigma}_c$ resonances in hot dense matter are shown in the l.h.s. of Fig. 1 for three different self-consistent calculations: i) including only the self-consistent dressing of the $D$ meson, ii) adding the mean-field binding of baryons (MFB) and iii) including MFB and the pion self-energy (PD). The thick lines correspond to model A (viz. $\Sigma_{DN} \neq 0$) while the thin-dashed lines refer to Case (iii) within model B ($\Sigma_{DN} = 0$). Medium effects at $T = 0$ lower the position of the $\tilde{\Lambda}_c$ and $\tilde{\Sigma}_c$ with respect to their free values. Their width values, which increase due to $\tilde{Y}_c(=\tilde{\Lambda}_c, \tilde{\Sigma}_c) N \to \pi N \Lambda_c, \pi N \Sigma_c$ processes, differ according to the phase space available. The PD induces a small effect in the resonances because of charm-exchange channels being suppressed, while models A and B are qualitatively similar. Finite temperature results in the reduction of the Pauli blocking due to the smearing of the Fermi surface with temperature. Both resonances move up in energy closer to their free position while they are smoothed out, as in [4].

In the r.h.s. of Fig. 1 we display the $D$ meson spectral function for (i) to (iii) (thick lines) for model A and case (iii) for model B (thin line). At $T = 0$ the spectral function presents two peaks: $\tilde{\Lambda}_c N^{-1}$ excitation at a lower energy whereas the second one at higher energy is the quasi(D)-particle peak mixed with the $\tilde{\Sigma}_c N^{-1}$ state. Once MFB is included, the lower peak built up by the $\tilde{\Lambda}_c N^{-1}$ mode goes up by about 50 MeV relative to (i) since the meson requires to carry more energy to compensate for the attraction felt by the nucleon. The same characteristic feature is seen for the $\tilde{\Sigma}_c N^{-1}$ configuration that mixes with the quasiparticle peak. The PD does not alter much the

Fig. 2. $\bar{D}$ mass shift as well as $T\rho$, and the $D$ and $\bar{D}$ potentials.
position of $\tilde{\Lambda}_cN^{-1}$ excitation or the quasiparticle peak. For model B ((iii) only), the absence of the $\Sigma_{DN}$ term moves the $\tilde{\Lambda}_cN^{-1}$ excitation closer to the quasiparticle peak, while the latter fully mixes with the $\tilde{\Sigma}_cN^{-1}$ excitation. At finite temperature those structures dilute with increasing temperature while the quasiparticle peak gets closer to its free value becoming narrower, because the self-energy receives contributions from higher momentum $DN$ pairs where the interaction is weaker.

In the $\bar{D}N$ sector, the scattering lengths for model A (B) are $a^{I=0} = 0.61 (0)$ fm and $a^{I=1} = -0.26 (-0.29)$ fm. While our repulsive $I = 1$ is in good agreement with [5], the finite value for the $I = 0$ scattering length found in this latter reference is in contrast to the zero value found here for model B due to the vanishing $I = 0$ coupling coefficient of the corresponding pure TW $\bar{D}N$ interaction. Our results are, however, consistent with Ref. [8]. For model A, we obtain a non-zero value of the $I = 0$ scattering length, due to the magnitude of the $\Sigma_{DN}$ term. As seen in the l.h.s of Fig. 2, the $\bar{D}$ mass shift in cold nuclear matter is repulsive and, in spite of the absence of resonances close to threshold, the low-density approximation or $T\rho$ breaks down at normal nuclear matter density $\rho_0 = 0.17 \text{ fm}^{-3}$.

Finally, in the r.h.s of Fig. 2 we compare the $D$ and $\bar{D}$ optical potentials. For model A (B) at $T = 0$, we obtain an attractive potential of $-12 (-18)$ MeV for the $D$ meson, similar to [4], while the repulsion for $\bar{D}$ is $11 (20)$ MeV. The temperature dependence of the repulsive real part of the $\bar{D}$ optical potential is very weak, while the imaginary part increases steadily due to the increase of collisional width. The picture is somewhat different for the $D$ meson due to the overlap of the quasiparticle peak with the $\tilde{\Sigma}_cN^{-1}$ mode. The $\tilde{\Sigma}_cN^{-1}$ mode also alters the effect of the $\Sigma_{DN}$ term on the potential.

3. Charm and hidden charm scalar resonances

Establishing the nature of a resonance, whether it has the usual $q\bar{q}/qqq$ structure or is better described as being dynamically generated, is an active matter of research, in particular, for scalar resonances. Via their renormalized properties in nuclear matter we can not only learn about the excitation mechanisms in the nucleus but also the properties of these particles.

We study the charmed resonances $D_{s0}(2317)$ and $D(2400)$ [9] [10] [11] together with a hidden charm scalar meson, $X(3700)$, predicted in [11], which might have been observed by the Belle collaboration [12] via the reanalysis of [13]. Those resonances are generated dynamically solving the coupled-channel Bethe-Salpeter equation for two pseudoscalars [14]. The kernel is derived from a $SU(4)$ extension of the $SU(3)$ chiral Lagrangian used to generate scalar resonances in the light sector. The $SU(4)$ symmetry is, however, strongly broken, mostly due to the explicit consideration of the
masses of the vector mesons exchanged between pseudoscalars \[11\].

The analysis of the transition amplitude close to each resonance for the different coupled channels give us information about the coupling of the resonance to a particular channel. The \(D_{s0}(2317)\) mainly couples to \(DK\) system, while the \(D_0(2400)\) to \(D\pi\) and, secondly, to \(D_s\bar{K}\). And the hidden charm state \(X(3700)\) couples most strongly to \(D\bar{D}\). Therefore, any change in the \(D\) meson properties in nuclear matter will have an important effect on these resonances. Those modifications are given by the \(D\) meson self-energy in nuclear matter, as discussed in Sec. \[2\] but supplemented by the \(p\)-wave self-energy through the corresponding \(YcN^{-1}\) excitations \[14\].

In Fig. 3, the resonances \(D_{s0}(2317)\) and \(D_0(2400)\) and \(X(3700)\) are shown by displaying the squared transition amplitude for the corresponding dominant channel at different densities. In the case of the \(D_{s0}(2317)\) and \(X(3700)\) resonances, which have a zero and small width, respectively, the medium effects lead to widths of the order of 100 and 200 MeV at normal nuclear matter density, correspondingly. The origin can be traced back to the opening of new many-body decay channels, as the \(D\) meson gets absorbed in the nuclear medium via \(DN\) and \(DNN\) inelastic reactions. For the \(D_0(2400)\), we observe an extra widening from the already large width of the resonance in free space. However, the large original width makes the medium effects comparatively much weaker than for the other two resonances \[14\]. In our model, we do not extract any clear conclusion for the mass shift. We suggest to look at transparency ratios to investigate those in-medium widths. This magnitude, which gives the survival probability in production reactions in nuclei, is very sensitive to the absorption rate of any resonance inside nuclei, i.e., to its in-medium width.
4. Summary and Outlook

We have studied the properties of $D$ and $\bar{D}$ mesons within a self-consistent coupled-channel approach for the experimental conditions expected at the CBM experiment at FAIR. The in-medium $\bar{D}$ mass increases by about $10-20$ MeV whereas the $D$ spectral function extends to lower "mass" due to the thermally spread $\tilde{Y}, N^{-1}$. However, it is unlikely to explain $J/\Psi$ suppression via the $D\bar{D}$ decay in hot dense matter. A more plausible hadronic contribution for the $J/\Psi$ suppression is the reduction of its supply from the excited charmonia, $\pi\psi(1P)$ or $\psi'$, which may find in the medium other competitive decay channels. We have also evaluated the renormalized properties in nuclear matter of the charm scalar $D_{s0}(2317)$ and $D(2400)$, and the predicted hidden charm $X(3700)$ resonances. Those resonances develop an important width in this dense environment. We conclude that the experimental analysis of those properties is a valuable test of the dynamics of the $D$ meson interaction with nucleons and nuclei, and the nature of those charm and hidden charm scalar resonances. Altogether, those results should stimulate experimental work in hadron facilities, in particular at FAIR [1], where the charm degree of freedom will be thoroughly investigated.
