Learning to Singulate Objects using a Push Proposal Network

Andreas Eitel, Nico Hauff and Wolfram Burgard

Abstract A key challenge for manipulation in unstructured environments is action selection. We present a novel neural network-based approach that separates unknown objects in clutter by selecting favourable push actions. Our network is trained from data collected through large-scale interaction of a PR2 robot with randomly organized tabletop scenes. The model is designed to propose meaningful push actions based on segmented RGB-D images. We evaluate our approach by singulating up to six unknown objects in clutter. We demonstrate that our method enables the robot to perform the task with a high success rate and a low number of required push actions. Our results based on real-world experiments show that our network is able to generalize to novel objects of various sizes and shapes, as well as to arbitrary object configurations. Highlights of our experiments can be viewed in the following video: https://youtu.be/jWbUJOrSacI

1 Introduction

Robot manipulation tasks such as tidying up a room or sorting piles of objects are a substantial challenge for robots, especially in scenarios with unknown objects. The objective of object singulation is to separate a set of cluttered objects through manipulation, a capability regarded as relevant for service robots operating in unstructured household environments. Further, the ability to separate unknown objects from surrounding objects provides great benefit for object detection, which still remains an open problem for overlapping objects. A key challenge of object singulation is the required interaction of multiple capabilities such as perception, manipulation and motion planning. Perception may fail because of occlusions from objects but also from occlusion by the manipulator itself. Manipulation actions such as grasping may also fail when attempting to manipulate objects that the perception systems fails to
Fig. 1: Our approach consists of a convolutional neural network that ranks a set of potential push actions based on a segmented input image in order to clear objects in clutter. The proposed pushes are executed using motion planning. Our push proposal network is trained in an iterative manner from large-scale interaction with cluttered object scenes.

correctly segment. Motion planning is particularly prone to errors when applied in unknown, unstructured environments.

Previous approaches for object singulation strongly incorporate the concept of object segments or even complete objects. Push action strategies are selected based on the current belief of the configuration of all segments or objects in the scene, an assumption that is not robust, since segments might merge and object detection might fail. We apply a different strategy that aims to relax the concept of segments and objects for solving the task at hand, making task execution less prone to modelling errors from the perception modules. Similar to recent approaches that operate directly on image inputs [16, 18] we aim for an end-to-end action selection approach that takes as input an RGB-D image of a tabletop scene and proposes a set of meaningful push actions using a convolutional neural network, as shown in Fig. 1.

Our primary contributions are: 1) a push proposal network (push-CNN), trained in an iterative manner to detect push candidates from RGB-D images in order to separate cluttered objects, 2) a method that samples potential push candidates based on depth data, which are ranked with our push-CNN, and 3) real-world experiments with a PR2 robot in which we compare the performance of our method against a strong manually-designed baseline.

We quantitatively evaluate our approach on two sets of real-robot experiments. These experiments involve tasks with four unknown objects and 25 different object configurations as well as a more challenging one with six unknown objects and 10 object configurations. In total the robot executed over 200 push actions during the evaluation and achieved an object separation success rate of up to 70%, which shows
Learning to Singulate Objects using a Push Proposal Network

that our Push-CNN is able to generalize to previously unseen object configurations and object shapes.

2 Related Work

Standard model-based approaches for object singulation require knowledge of object properties to perform motion planning in a physics simulator and to choose push actions accordingly [5, 6]. However, estimating the location of objects and other properties of the physical environment can be subject to errors, especially for unknown objects [25]. Interactive model-free methods have been applied to solve the task by accumulating evidence of singulated items over a history of interactions including push and grasp primitives [4, 12, 9]. Difficulties arise when objects have to be tracked after each interaction step, requiring small motion pushes due to partial observations and occlusions. We follow a model-free approach that encodes evidence of singulated objects in the learned feature space of the network. Hermans et al. [12] perform object singulation using several push primitives similar to ours. Their method is based on object edges to detect splitting locations between potential objects to apply pushes in those regions respectively, but does not include learned features and does not take into account stacked objects. Katz et al. [13] present an interactive segmentation algorithm to singulate cluttered objects using pushing and grasping. Similar to them, we also create object hypothesis from segmentation of objects into surface facets but use a different method based on the work of [22]. Given the segmentation the authors perform supervised learning with manual features to detect good manipulation actions such as push, pull and grasp. We take the idea of learning a step further by directly learning from segmented images and therefore removing the need for manual feature design. Gupta et al. [9] present an approach to sort small cluttered objects using a set of motion primitives, but do not show experiments with objects of various size and shapes. Our approach is related to robot learning from physical interaction [20], including approaches that learn to predict how rigid objects behave if manipulated [15, 11] and self-supervised learning methods for grasping [21, 17]. Gualtieri et al. [8] present a grasp pose detection method in which they detect grasp candidates using a convolutional neural network. They follow a similar methodology but for a different task and goal. Recent methods learn the dynamics of robot-object interaction for the task of pushing objects to a target location [7, 1], but do not evaluate on scenes with many touching objects and do not follow an active singulation strategy. Byravan et al. [3] learn to predict rigid body motions of pushed objects using a neural network, but do not demonstrate results for multiple objects in a real-world scenario. Object separation is used as a source to leverage perceptual information from interaction following the paradigm of interactive perception [2]. As demonstrated in our experiments, our singulation method can be used to generate informative sensory signals that lower the scene complexity for interactive object segmentation [23, 10, 24].
3 Learning to Singulate Objects

We consider the problem of learning good push actions to singulate objects in clutter. Let $o$ be an image with height $H$ and width $W$ taken from a RGB-D camera with a known camera intrinsics matrix $K$. Further, let $a = (c, \alpha)$ be a push proposal with start position $c = (x, y)$ and push angle $\alpha$ both specified in the image plane. We aim to learn a function $p = F(o, a; \theta)$ with learned parameters $\theta$ that takes as input the image together with a push proposal and outputs a probability of singulation success.

3.1 Data

The prediction function $F$ is trained in an iterative manner (we use three iterations $F_0, F_1, F_2$) on experiences that the robot collects through interaction with the environment. At the first iteration, we gather a dataset $D$ of push proposals together with images from randomly pushing objects in simulation. Then, we train a classifier $F_1$ that best mimics the labels from an expert user in terms of successful and unsuccessful singulation actions. In the next iteration, we use $F_1$ to collect more data and add this data to $D$. The next classifier $F_2$ is trained to mimic the expert labels on the whole dataset $D$. We refer to $F_1$ as a vanilla network that is trained solely on experience collected from random interaction and $F_2$ as an aggregated network. The training examples $D = \{ (o_1, a_1, y_1), \ldots, (o_N, a_N, y_N) \}$ are labeled by an expert user, where $y_i$ is a corresponding label in one-hot encoding. The function is trained in a supervised manner using a negative log likelihood loss $\min_{\theta} \sum_{i=1}^{N} L(p, y^i)$ and a softmax function.

3.2 Approach

Our approach is divided into three modules, as shown in Fig. 1: 1) a sampling module that generates a set of push proposals, 2) a neural network module that classifies the set of push proposals and ranks them accordingly, and 3) an action execution module that first finds arm motion plans for the proposed pushes and then executes the push proposal with the highest probability of singulation success.

3.2.1 Push Proposal Sampling

Our push proposal sampling method is designed to generate a set of push proposals $\{a_1^1, \ldots, a_M^M\}$. First, we sample 3D push handles $\{h_1^1, \ldots, h_M^M\}$ represented as point normals pointing parallel to the xy-plane of the robot’s odometry frame $h_m^i = (x, y, z, n_h_i)$, $n_h_i = (-n_x, -n_y, 0)$. Specifically, given the raw depth image we
Fig. 2: We encode \( o \) and \( a \) together in a push proposal image \( o_a \) that maps both the configuration of the objects in the scene and the push proposal direction into a ‘push centric’ frame.

first apply a surface-based segmentation method \[22\] to obtain a set of segments \( \{s^1, \ldots, s^L\} \) together with a surface normals map and a table plane. Second, we sample for each segment \( s^l \) a fixed number of push handles and remove push handles below the table plane. Finally, we obtain a set of push proposals by transforming the push handles into the camera frame using the transformation matrix \( C \) from the odometry to the camera frame together with the camera intrinsics \( a = KCh \).

### 3.2.2 Push Proposal Network and Input

We parametrize the predictor \( F(o, a; \theta) \) using a deep convolutional neural network, denoted as a push proposal CNN in Fig. 1. The distinction between \( o \) and \( a \) as input is somewhat artificial, because both inputs are combined in a new image \( o_a \) which constitutes the final input of the network. To predict the probability of success of a push proposal for the given singulation task the most important feature is the relation of the candidate segment that we want to push and its relation to neighbouring segments. We propose to fuse the segmented camera image with a push proposal using rigid image transformations \( T_t, T_r \), see Fig. 2. First, we transform the image by a rigid translation \( T_t (c) \) according to the start position \( c \) of the push proposal. Second, we apply image rotation \( T_r (\alpha) \) according to the push angle \( \alpha \). The resulting image is \( o_a = T_r T_t o \), as depicted in the right image of Fig. 2. The input to the network is a single channel grayscale version of the transformed image \( o_a \) with a resolution of \( 64 \times 64 \) pixels. Our push proposal network consists of five convolutional layers and two fully-connected layers, as shown in Fig. 3. At test time we forward the set of transformed input images \( \{o_a^1, \ldots, o_a^M\} \) into the network to predict a probability of success for each push proposal in the set \( \{a^1, \ldots, a^M\} \).
3.2.3 Push Motion Planning

To find a motion plan for each push proposal we use the default motion planning algorithm LBKPIECE provided by the MoveIt motion planning framework. Our arm motion strategy consists of two steps. In the first step, we plan to reach the target push proposal \( a^m \). In a second step, given that the gripper reached the desired push start position, the robot performs a straight line push with a fixed length of 0.2m. We compute motion plans for both steps before execution to avoid that the robot executes the reaching plan and then fails to find a plan for the straight line push. We found our two-step procedure to be more stable than executing a reach and push trajectory at once, due to arm controller errors.

4 Experiments

We conduct both qualitative and quantitative experiments on a real PR2 robot to benchmark the performance of our overall approach. Hereby, we aim to answer the following questions: 1) Can our push proposal network predict meaningful push actions for object shapes and configurations it has not seen during training? 2) Can our network trained in simulation generalize to a real-world scenario? 3) Can our model reason about scene ambiguities including multiple object clusters and focus its attention to objects that are more cluttered than others? In order to answer question (1) we perform real-world experiments with objects that the network has not seen during training and compare against a manual model-free baseline that reasons about available free space in the scene and keeps a history of previous actions. To answer question (2) we test a network that we train solely with data from simulation (de-

![Fig. 4: Starting configurations of the 25 test trials with four objects.](image-url)
noted as vanilla network). Finally a challenging experiment with six objects aims to answer question (3), where the learned model has to trade-off between further separating isolated objects to create more space and split isolated object clusters to solve the task. The overall intent of our experiments, is to show that a learned model is able to directly map from sensor input to a set of possible actions, without prior knowledge about objects, spatial relations or physics simulation.

4.1 Network Training

To train our push proposal network we use an iterative training procedure. First, a vanilla network is trained on labeled data from a total of 2,486 (243 positives, 2,243 negatives) random interactions performed in simulation. Then an aggregated network is trained on additional 970 interactions (271 positives, 699 negatives), which we collected using the vanilla network in both simulation and real-world, resulting in a training dataset size of 3,456 push interactions. Both networks are trained in a fully-supervised manner from scratch using random uniform weight initialization and Adam [14]. We performed network architecture search with 10 different configurations and found that for our task the network architecture depicted in Fig. 3 yielded best performance on two separate validation sets. We experienced a drop in classification performance when increasing the image size, introducing dropout, or removing pooling operations, and did not experience improvement for adding xavier weight initialization or other activation functions besides ReLUs. Finally, we trained our model for 25 epochs with a batch size of 64, using the default parameters for Adam (learning rate\(=0.001\), \(\beta_1 = 0.9\), \(\beta_2 = 0.999\), \(\varepsilon = 1e-08\), decay = 0.0).

We use the object dataset by Mees et al. [19] for our simulation experiments.

4.2 Experimental Setup

Our PR2 robot is equipped with a Kinect 2 camera mounted on its head that provides RGB-D images with a resolution of 960 \(\times\) 540. We use both arms of the robot, each with 7-DOF to perform the pushing actions. The task is designed as follows: a trial consists of four or six objects from a test set of 11 everyday objects with different shapes. In the starting configuration for a trial all objects are placed or stacked on a table to be in collision. The starting configurations are saved and reproduced for all methods in a manual manner using point cloud alignment. The 25 starting configurations for our quantitative evaluation with four objects are depicted in Fig. 4.

We report the number of successful singulation trials. A singulation trial is considered successful if all objects are separated by a minimum distance of 3cm. Further, we report results for singulation success after every action, to show which methods can successfully execute the task with less actions. For each trial the robot performs a fixed set of actions. The robot is allowed to stop before, if it reasons that
all objects are singulated. This is implicitly encoded into our method. If the robot
does not find a motion plan for the set of push proposals that the network ranked as
positive it automatically terminates the trial.

4.3 Baseline Method

We provide a quantitative comparison against a manually designed baseline method,
to evaluate whether or not the predictions of the push proposal network lead to im-
proved object singulation results. We do not provide knowledge about the objects
and their physical properties to our model, correspondingly our baseline method is
model-free and follows an interactive singulation strategy that is reasonably effec-
tive. The method which we denote as 'free space + tracking' works as follows:

1. Given a set of segments \( \{s^1, \ldots, s^L\} \) from our object segmentation approach we
   construct a graph that includes all segments, where each segment is a node in the
   graph and the edges correspond to distances between the segments. We represent
   each segment as an axis-aligned bounding box (AABB) and compute an edge
   between two segments by means of the Manhattan distance of the two AABBs.

2. We compute two features for scoring push proposals with the baseline method.
   The first feature is a predictive feature that reasons about the resulting free space
   if a segment would be pushed to some target location. To compute the feature,
   we predict a straight line motion of the respective segment to which the push
   proposal is assigned to, according to the push direction and the length. Next,
   we compute the Manhattan distance between the resulting transformed AABB
   and all other segments in the scene, which we assume will remain static. The
   free space feature \( f_s \) is the minimum distance between the transformed AABB
   and the other AABBs. If the predicted final position of a segment would lead to
   collision with another segment the free space feature is zero.

3. The second feature includes the push history that we store for each segment.
   It follows the intuition that the same segment should not be pushed too often,
   regardless of the predicted free space around it. To retrieve the push history over
   all segments, we follow a segment-based tracking approach, which aligns the
   centroid and the principal components of two segments from the current set of
   segments and the set of segments from the last interaction, similar to [4]. We
   match a set of segments using a weighted average of the principal components
   and the segment centroid distances \( d'(s', s'') = 0.6 \cdot d_{pca}(s', s'') + 0.4 \cdot d_c(s', s'') \).
   To punish multiple pushes \( r \) of a segment throughout a trial we map the push
   motion history into a normalized feature using an exponential decay function
   \( f_h = \exp(-r) \).

4. Accordingly, a push proposal \( a^m \) receives the score \( p^m = 0.5 \cdot f_s + 0.5 \cdot f_h \).
4.4 Quantitative Comparisons

Our results with four objects, shown in Table 1, indicate that our method is able to improve over the performance of the manual baseline. The success rate of our vanilla network is 68%, which suggests that the model is making meaningful predictions about which push actions to perform in order to singulate all four objects. Fig. 5 provides a more fine-grained evaluation, showing the success rate with respect to the number of pushes. Note that the network requires less push actions to complete the task. Interestingly, the baseline method performs on par with the network after the robot has executed five push actions, but then it does not further improve after six executed pushes. We noted that the baseline method sometimes fails to singulate the last two objects of the scene and instead will choose an object that might already be singulated because it lacks a good attention mechanism.

Results in Table 2 show that the task is more complex with six objects, due to additional space constraints and formation of multiple object clusters. When looking at the scene in Fig. 1, four out of the six objects are located very closely on the table (green drink bottle, blue box, white round bowl, white coffee bag). Although there are many possible push actions that we would consider reasonable, only pushing the coffee bag or the round bowl to the left side of the table can clear the scene. Accordingly, we find that the performance of the vanilla network drops with respect to the previous experiment with four objects. During training it has only seen a small amount of scenes where a random baseline would have cleared all but two

| Method                  | Success/total | Success rate | Mean number of pushes |
|-------------------------|---------------|--------------|-----------------------|
| Free space + tracking   | 14/25         | 56%          | 5.4±1.68              |
| Vanilla network         | 17/25         | 68%          | 4.96±1.84             |

Fig. 5: Success rate with respect to number of pushes (max. 6) required to clear four objects.
Table 2: Object singulation results on 10 test trials with six objects.

| Method                  | Success/total | Success rate | Mean number of pushes |
|-------------------------|---------------|--------------|-----------------------|
| Free space + tracking   | 4/10          | 40%          | 7.8±1.61              |
| Vanilla network         | 4/10          | 40%          | 8.1±1.37              |
| Aggregated network      | 7/10          | 70%          | 6.7±2.0               |

Fig. 6: Success rate with respect to number of pushes (max. 8) required to clear six objects.

objects and even less likely has seen examples where the robot by chance chose the right action to clear the two remaining objects. Therefore, in this scenario the vanilla network and the baseline method perform on par with a success rate of 40%. When comparing the average number of pushes the baseline performs slightly better, see Fig. 6. Results show that the aggregated network clearly outperforms the other two methods, winning seven out of ten trials with an average of 6.7 push actions needed to singulate all six objects, as shown in Table 2. To get an intuition about the numerical results we refer the reader to the performance reported by Hermans et al. [12], who evaluated a very similar task with six objects. They report a success rate of 20% with twelve average number of push actions.

4.5 Qualitative Results

Fig. 7 gives insights about the singulation trials from the perspective of the Kinect camera. The first and the third column shows the current scene, while the second and fourth column shows the robot performing a push action. The trial evolves from top to bottom of the figure.
Learning to Singulate Objects using a Push Proposal Network

Fig. 7: On the left, we see a successful trial. Note that the robot tries several times to clear a small plastic bottle which is stuck under a blue box and manages to singulate the objects in the very last action. On the right we see a run that fails because of two typical reasons: First, the robot is not able to perform a save push action (fourth column, fifth row), which results in two objects moving more closely together (blue box, cereal box). Second, the network is not able to draw its attention to the same two objects that are now touching and instead proposes an action that moves the green bottle further away from the scene (lower right image).

5 Conclusions

We presented a novel neural network-based approach to singulate unknown objects in clutter by means of pushing actions. Our push proposal network is able to reason about the scene based on segmented images from an RGB-D camera and predict which push action to perform in order to clear a set of objects with various sizes and shapes. We tested our method in extensive real-robot experiments using a PR2 robot and showed the ability of our method to achieve good performance for the task of singulating up to six objects.
