We study the ac anomalous Hall conductivity $\sigma_{xy}(\omega)$ of a Weyl semimetal with broken time-reversal symmetry. Even in the absence of free carriers these materials exhibit a “universal” anomalous Hall response determined solely by the locations of the Weyl nodes. We show that the free carriers, which are generically present in an undoped Weyl semimetal, give an additional contribution to the ac Hall conductivity. We elucidate the physical mechanism of the effect and develop a microscopic theory of the free carrier contribution to $\sigma_{xy}(\omega)$. The latter can be expressed in terms of a small number of parameters (the electron velocity matrix, the Fermi energy $\mu$, and the “tilt” of the Weyl cone). The resulting $\sigma_{xy}(\omega)$ has resonant features at $\omega \sim 2\mu$ which may be used to separate the free carrier response from the filled-band response using, for example, Kerr effect measurements. This may serve as diagnostic tool to characterize the doping of individual valleys.

![Free carrier pockets](image)

**Fig. 1:** Projection of generic band structure with Weyl points close to the chemical potential. Free carriers are localized to electron (green) or hole (red) pockets near the Weyl nodes.

As a result the Kubo formula for the optical conductivity may be expressed as a sum over quasimomenta

$$\sigma_{\alpha\beta}^{(free)}(\omega) = \sum_p \sigma_{\alpha\beta}(\omega, p) [n_+(p) - n_-(p) + 1], \quad (2)$$

where $n_+(p)$ denotes the Fermi occupation function in the conduction/valence band, and by $\sigma_{\alpha\beta}(\omega, p)$ we denote the matrix elements and energy denominators. The filled band contribution in Eq. (1) has the form,

$$\sigma_{\alpha\beta}^{(band)}(\omega) = \sum_p \sigma_{\alpha\beta}(\omega, p) \times (-1).$$

Below we focus on the free carrier contribution, $\sigma_{\alpha\beta}^{(free)}(\omega)$ in Eq. (2). Since the occupation factor in this term, $[n_+(p) - n_-(p) + 1]$, is nonzero only close to the Weyl nodes, $\sigma_{\alpha\beta}^{(free)}(\omega)$ may be written as a sum of partial contributions of individual Weyl nodes, $\sigma_{\alpha\beta}^{(n)}(\omega)$, see Eqs. (3) and (4) below. The latter may be expressed in terms of the Fermi energy in the node, $\mu$, and the parameters of the Weyl Hamiltonian describing the electron dynamics near the node,

$$\mathcal{H}(p) = \mathbf{u} \cdot \mathbf{p} \sigma_0 + v_{ij} p_i \sigma_j. \quad (3)$$
It is useful to see how a nonvanishing free carrier Hall response arises in the framework of Eq. (2). Note that tilting the energy dispersion by \( u \) amounts to a mere energy shift of the two-state system defined at each \( p \) and thus affects neither the matrix elements nor the energy denominators, i.e. \( \sigma_{\alpha\beta}(\omega, p) \) is independent of the tilt. In the absence of \( u \) the only vector breaking time reversal symmetry is the momentum \( p \). Thus by the Onsager symmetry principle, \( \sigma_{\alpha\beta}(\omega, p) = \sigma_{\beta\alpha}(\omega, -p) \), the Hall response must be odd in \( p \). It might seem that upon the integration over momentum this would give a vanishing result \(^{34}\), however this is not the case. The occupation factor in Eq. (2) depends on the tilt velocity \( u \), which makes it asymmetric in \( p \), see Fig. 2. As a result the momentum sum in Eq. (2) is nonzero. Physically the nonvanishing Hall response of free carriers arises due to asymmetric in \( p \) Pauli blocking of the filled band response. In a similar fashion asymmetric blocking leads to photocurrents in WSMs \(^{35}\).

Note that the occupation factor is asymmetric in \( p \) if and only if the node is tilted and the Fermi energy does not lie exactly at the nodal point. It is asymmetric in the region of momenta \( p \in [p_{\min}, p_{\max}] \) with \( p_{\min}/p_{\max} = |\mu|/v_f(1 \pm U) \) (here \( U \) is the magnitude of the tilt velocity in units of the Fermi velocity and for simplicity \( v_{ij} = \chi v_f \delta_{ij} \).

Let us now proceed with quantitative consideration. For brevity we set \( \hbar = c = 1 \) in intermediate steps. The Kubo formula relates the optical conductivity to the retarded current-current correlation function

\[
\sigma_{\alpha\beta}(\omega) = \frac{i}{\omega} \Pi_{\alpha\beta}^{\text{Ret}}(\omega). \tag{4}
\]

The retarded correlator \( \Pi_{\alpha\beta}^{\text{Ret}}(\omega) \) is obtained from the Matsubara current-current correlation function

\[
\Pi_{\alpha\beta}(i\omega_n) = \frac{T}{V} \sum_{m,p} \text{tr} [j_\alpha G(i\epsilon_m + i\omega_n, p) j_\beta G(i\epsilon_m, p)] \tag{5}
\]

by analytic continuation to real frequencies, \( i\omega_n \rightarrow \omega + i0 = \omega_+ \). In Eq. (5) \( T \) denotes temperature, \( V \) volume and the trace is taken over the spinor indices. The Matsubara Green function corresponding to Hamiltonian \(^{[3]}\) is

\[
G(i\epsilon_n, p) = \frac{(i\epsilon_n - u \cdot p)\sigma_0 + v_{ij} p_i \sigma_j}{(i\epsilon_n - E_+(p)) (i\epsilon_n - E_-(p))}, \tag{6}
\]

and the current operator is given by

\[
j_\alpha = -\frac{\delta}{\delta A_\alpha} \mathcal{H}(p - eA) = e (u_\alpha \sigma_0 + v_{\alpha j} \sigma_j). \tag{7}
\]

To simplify notation we rescale momenta, \( l_j = v_{ij} p_i \), and the tilt velocity, \( \chi U_i = v_{ij}^{-1} u_j \), where we have factored out the chirality in order to consider the effect of tilt and chirality separately. Performing the frequency summation in Eq. (5) and subtracting the filled band contribution as

---

**FIG. 2:** Projection of the dispersion close to a generic Weyl node for \( u[p_{\mu} \text{ and } v_{ij} = v_f \delta_{ij} \). The Fermi-surface forms an ellipse centered away from the nodal point. The occupation factor \( n_+(p) = n_-(p) + 1 \) is non-zero whenever transitions at a given momentum are blocked. It is asymmetric in \( p \) for \( p_{\min} < p < p_{\max} \) (above \( p_{\max} \) all transitions are allowed, below \( p_{\min} \) all are blocked). Frequencies \( \omega_{\min} < \omega < \omega_{\max} \) correspond to transitions for which only part of the spectrum is Pauli blocked.

Here \( \sigma_{ij} \) are the Pauli matrices, the velocity matrix \( v_{ij} \) is real symmetric, and the velocity \( u \) describes the tilt of the energy cone \(^{33}\). The index \( n \) labelling the nodes has been omitted in these expressions. The corresponding energy spectrum, \( E_{\pm}(p) = u \cdot p \pm \sqrt{\sum_j (v_{ij} p_i)^2} \) is shown in Fig. 2.

Before proceeding with quantitative consideration we discuss qualitatively the physical origin of the nonvanishing anomalous Hall response \( \sigma_{\text{free}}^{(\text{free})}(\omega) \). First we note that a finite Hall conductivity of an individual Weyl node is allowed by symmetry. It corresponds to the antisymmetric part of the conductivity tensor, \( \sigma_{\alpha\beta} \), and is proportional to \( \varepsilon_{\alpha\beta\gamma} u_\gamma \). Here the tilt velocity \( u \) breaks the time reversal symmetry of a given node, and the Levi-Civita tensor \( \varepsilon_{\alpha\beta\gamma} \) is provided by the chirality of the Weyl node (which is given by \( \chi = \text{sgn}(\text{det} \nu) \)). Although the above argument applies to both time-reversal invariant and noninvariant WSMs in the former the Hall contributions of Weyl nodes related by TR symmetry cancel each other. Indeed, the Hamiltonian of a TR partner may be obtained from Eq. (3) by making the substitution \( u \rightarrow -u \). This does not change the chirality of the node but changes the sign of the Hall response. In TR breaking WSMs such a cancellation does not occur and the Hall responses of individual nodes do not sum up to zero. Similarly, the responses of nodes linked by inversion symmetry generally add up as both \( u \) and \( \chi \) change sign.
explained above, we obtain the free carrier contribution to the conductivity from an individual node,

\[
\sigma^{(n)}_{\alpha\beta}(\omega) = \sum_l \sigma^{(n)}_{\alpha\beta}(\omega, l) \left[ n_+^{(n)}(l) - n_-^{(n)}(l) + 1 \right].
\]  

(8)

In this expression \( n^{(n)}_\pm(l) = n_f(\chi_l \cdot U \pm l - \mu) \) and

\[
\sigma^{(n)}_{\alpha\beta}(\omega, l) = \frac{1}{V} \frac{2ie^2 v_{\alpha i} v_{\beta j}}{|\det v|} \frac{2\delta_{ij} - 2l_i l_j + i\omega + \varepsilon_{ijk} l_k}{\omega l(4\omega^2 - \omega_l^2)},
\]

where the sum now is over rescaled momenta \( l \). The symmetry arguments discussed above are manifest in this expression: the Hall (antisymmetric in \( \alpha\beta \)) response arises from the term \( \propto \varepsilon_{ijk} \), and exists only if \( U \) is nonzero, since otherwise the occupation factor is symmetric under \( l_k \to -l_k \). Changing \( l \to \chi l \) we observe that only the antisymmetric term is sensitive to the chirality of the node. The same applies to change of sign of the tilt velocity. Moreover, we see that Hall response arises even for the isotropic velocity matrix \( v_{ij} \propto \delta_{ij} \); the anisotropy of \( v_{ij} \) merely amounts to anisotropic rescaling. Therefore the contribution of valley \( n \) to the optical conductivity tensor may be expressed in the form

\[
\sigma^{(n)}_{\alpha\beta}(\omega) = \frac{v_{\alpha i} \sigma^{(n)}_{\alpha\beta}(\omega)}{v_f} v_{\beta j},
\]

(10)

where \( v_f^3 = |\det v| \) and \( \sigma^{(n)}_{\alpha\beta}(\omega) \) is the response corresponding to the isotropic case, \( v_{ij} = \chi v_f \delta_{ij} \). It is useful to note that after rescaling \( U \) is the only available vector breaking rotational invariance in the single-node problem. This allows to express the components of \( \sigma \) in terms of universal functions \( f^{(n)} \) depending only on the parameters of node \( n \) such that

\[
\sigma^{(n,\text{Hall})}_{ij}(\omega) = \varepsilon_{ijk} \tilde{U}_j f^{(n)}_{\text{Hall}}(\omega),
\]

(11a)

\[
\sigma^{(n,\perp)}_{ij}(\omega) = (\delta_{ij} - \tilde{U}_i \tilde{U}_j) f^{(n)}_{\perp}(\omega),
\]

(11b)

\[
\sigma^{(n,\parallel)}_{ij}(\omega) = \tilde{U}_i \tilde{U}_j f^{(n)}_{\parallel}(\omega),
\]

(11c)

where \( \tilde{U} = U/U, \ U = |U| \). We assume \( U < 1 \), i.e. only consider type-I WSMs [30]. As we wish to obtain closed form solutions we take the zero temperature limit. For details of the calculation see the supplemental material. Restoring \( \hbar \) we obtain for the frequency dependence of the free carrier conductivity of an individual node \( n \)

\[
f^{(n)}_{\text{Hall}}(\omega) = \frac{-\chi \pm \text{sgn}(\mu)\epsilon^2}{16\pi^2 \hbar v_f U^2} \left[ |\mu|(L_1 + 2U) + \frac{1 - U^2}{4\omega} + \frac{|\mu|^2}{\omega} \right] L_2 \]

(12)

\begin{align*}
\text{Im}(\rho^{(n)}_{\text{Hall}}) \\
\text{Re}(\rho^{(n)}_{\text{Hall}}) \\
\text{Im}(\Sigma_{\text{Hall}}^{(n)})
\end{align*}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig3.png}
\caption{Frequency dependence of the free carrier AH conductivity for a single node with \( U = 0.2 \) and \( \mu = v_f = 1 \). The imaginary part (solid orange) is non-zero only in the intervals \( \omega_{\text{min}} < \omega < \omega_{\text{max}} \). The width of this region is determined by tilt and chemical potential. The dot-dashed red graph shows the response of a system of four nodes with \( \mu = (0.5, 0.9, 1, -1.4) \) and tilts \( U = (0.3, 0.05, 0.2, 0.05) \). The nodes with \( \mu = 0.9, 1.4 \) have \( \chi = -1 \). Here, charge neutrality was ignored for simplicity.}
\end{figure}

\begin{align*}
\omega_{\text{min}} &= \frac{2|\mu|}{\omega_{\text{max}} - \omega_{\text{mini}}} & \omega_{\text{max}} &= \frac{2|\mu|}{\omega_{\text{max}} - \omega_{\text{maxi}}}, \\
\omega_{\text{maxi}} &= \frac{2|\mu|}{\omega_{\text{maxi}} - U} & \omega_{\text{maxi}} &= \frac{|\mu|}{U}.
\end{align*}

and also \( \omega_{\text{min/i maxi}} = 2|\mu|/(1 \pm U) \) for the limiting frequencies of partially blocked transitions, c.f. Fig. 2.

Equations (10) - (14) are the central results of this paper [37]. In particular Eq. (12) gives the frequency dependence of the free carrier contribution to the AHE, which is depicted in Fig. 3. The imaginary part arises from real optical transitions that are asymmetrically Pauli-blocked. It exists only in the frequency interval \( \omega_{\text{min}} < \omega < \omega_{\text{max}} \). The real part exhibits a resonant structure at frequencies \( \pm \omega_{\text{min/i maxi}} \). The red and dot-dashed graph shows the imaginary part of the free carrier Hall conductivity in a four node system given by the sum of individual node contributions.
Due to the gapless character of the electron spectrum the filled band contribution to the permittivity \( \epsilon_{xx}^{(\text{band})}(\omega) \) has a logarithmic frequency dependence at low frequencies of interest. Since this dependence arises from the low energy electron excitations described by the Weyl Hamiltonian \( \mathcal{H} \) it may be described in terms of the parameters of the Weyl nodes. A consideration similar to that of the free carrier contribution yields for isotropic valleys with Fermi velocities \( v_n \)

\[
\epsilon_{xx}^{(\text{band})}(\omega) = \epsilon_\infty + \frac{e^2}{6\pi^2\hbar} \sum_{n} \frac{1}{v_n} \ln \left( \frac{\Lambda^2}{\omega_0^2} \right).
\]

The frequency cut-off \( \Lambda \) can be absorbed in the permittivity of inert bands \( \epsilon_\infty \). For details see the supplemental material.

Figure 4 shows a characteristic Kerr spectrum for a WSM with four nodes. The presence of free carriers at node \( n \) leads to resonances in the Kerr angle which are (skewly) centered around \( \omega = 2\mu_n \) with width \( U_n \mu_n/(1 - U_n^2) \). The sign of the peaks is given by the product of chirality, projection of tilt along \( e_z \) and the sign of the chemical potential. The peak at low frequencies occurs at the plasmon frequency \( \omega_p \) that corresponds to vanishing permittivity. If the plasmon response occurs at larger frequencies than free carrier features both free carrier and plasmon peak will remain present but change in shape. As is clear from the graphs, the universal contribution to the AHE merely modifies the shape of the resonant features in the frequency dependence of the Kerr angle, while their locations are determined purely by the free carrier contribution. This allows to experimentally determine the doping level of individual valleys.

Note that extrapolation of our result for \( \sigma_{xy}^{(n)}(\omega) \) to the \( dc \) limit \( \omega \to 0 \) gives a finite result: assuming isotropy and \( u \parallel e_z \),

\[
\sigma_{xy}^{(n)}(0) = f_{\text{Hall}}^{(n)}(0) = \frac{-\chi e^2}{8\pi^2\hbar v_f} \left( \frac{2}{U} + \frac{1}{U^2} \ln \left( 1 - \frac{1}{U} \right) \right).
\]

This result is purely formal, as in the presence of impurities our results only apply in the collisionless regime \( \omega \tau \gg 1 \), where \( \tau \) is the transport mean free time. Nevertheless, in the \( dc \) regime \( \omega \tau \ll 1 \) the free carrier contribution to the AHE should remain finite. For high mobility conductors it is expected to be dominated by skew scattering of Weyl fermions and may be estimated as

\[
\sigma_{xy}^{(n,sk)} \propto \frac{\tau^2}{\tau_{sk}} \frac{e^2}{\hbar^2 v_f} \eta(U).
\]

Here \( 1/\tau_{sk} \) is the skew scattering rate. Note that skew scattering is allowed by symmetry. For example, chirality allows to write the intranode skew scattering cross-section in the form \( w_{sk} \propto u \cdot (k \times k') \). It arises only beyond the lowest Born approximation for the scattering amplitude. In this respect it is worth noting that in Ref. \( 34 \) the effects of energy cone tilt on Pauli blocking and impurity skew scattering were not considered. This resulted in a vanishing free carrier contribution to the anomalous Hall conductivity.

In conclusion, we note that the developed microscopic theory of ac anomalous Hall conductivity, and its implications for the magneto-optical Kerr effect, apply not
only to WSMs with spontaneously broken TR symmetry, but are also relevant for systems in which the WSM phase is “created” \[\text{[10]}\] by application of a magnetic field to TR-invariant Dirac semimetals. We would also like to note that the diagonal components of the conductivity tensor have features at $\omega \sim 2\mu$. Thus, in TR-invariant Weyl semimetals the doping levels of individual valleys may be characterized by measuring the frequency dependence of the surface impedance.

[33] These parameters are not fully independent but are subject to the constraints set by the Nielsen-Ninomiya theorem, crystal symmetries and charge neutrality. Note that node $n$ contributes carrier density

$$n(\mu_n, U_n, v_n) = \frac{2 \mu_n^3}{3(1 - U_n^2)^2}.$$  

For an undoped crystal the charge neutrality condition corresponds to $\sum_n n(\mu_n, U_n, v_n) = 0$. Here $v_{n\alpha} = v_n \delta_{n\alpha}$ and $U$ is the absolute value of the tilt velocity in units of $v_n$.

[36] The free carrier contribution to the conductivity of type-II WSM requires a different treatment since here the Fermi surface is not well captured by a single node model [41].

[37] If in addition to the Weyl nodes there are further carrier pockets of different nature, these equations give the partial contribution due to the Weyl nodes.

[38] The expression in Eq. (15) assumes local response (absence of spatial dispersion) and ignores the contribution of the Fermi arcs. The first assumption is valid because the electron displacement during the oscillation period $\sim v/\omega$ is smaller than the skin depth in a Weyl semimetal $\delta = c/\sqrt{2\pi\omega\sigma_{xx}(\omega)} \sim c/\omega$. A straightforward calculation based on the Fermi golden rule shows that the contribution of arc states to the energy absorption rate is smaller than that of bulk states in $v/c$. Since the ratio of the Hall response to the diagonal response is independent of $v/c$ the arc state contribution to the Kerr effect is also small.
